

INDEX TO VOL. LXXII

OF

"THE INDIAN MEDICAL GAZETTE"

For the year 1937

[Original Article 'O.A.'; Mirror of Hospital Practice 'H.P.'; Editorial 'E.'; Special Article 'S.A.'; Medical News 'M.N.'; Commentaries 'Com.'; Current Topics 'C.T.'; Correspondence 'C.'; *Italics* signify Reviews; Reviews are placed under the name of the author; they also appear under the heading 'Reviews', where they are arranged according to subjects.]

	Page		Page		Page
A		Anæmia, Epidemic Dropsy and Malaria, The Bisulphate-Binding Power of the Blood in Cases of, and its possible bearing on a Vitamin-B Deficiency (Wilson and Ghosh) (O. A.) ..	147	Antimony, A Stable Solution of, for the Treatment of Kala-Azar (Napier, Chaudhuri and Rai Chaudhuri) (O. A.) ..	462
Abdominal Pain (Ogilvie) (C. T.)	632	—of Pregnancy (Mittra) (O. A.) ..	586	—Trichloride Test, in the Livers of Malnourished Children, Vitamin A, as Determined by the Blue Units of the (Nicholls) (O. A.) ..	293
Abrahams, M., and other. <i>The Modern Dietary Treatment</i> ..	442	—in Tea Garden Labour Forces (Napier) (O. A.) ..	270	Anti-mosquito Campaign, Delhi (Covell) (M. N.) ..	250
Abscess, Pelvic (Soldenhoff) (H. P.) ..	550	—Treatment of (E.) ..	369	Anti-rabic Treatment, A Case of Paraplegia and Hydrophobia following a full Course of (Nath) (C.) ..	127
Accident, An Unusual Result of an (Mehta) (C.) ..	327	Anæsthesia, Sodium Evipan (Dey) (O. A.) ..	408	Anus, Congenital Obstruction of the (Hariharan) (H. P.) ..	416
Actinomycosis, The Treatment of (Bates) (C. T.) ..	636	—Spinal (Malik) (O. A.) ..	609	Anwar, S. M. Osteomalacia; Torsion of the Pregnant Uterus (H. P.) ..	30
Aden, <i>Brucella abortus</i> Infection in (Phipson) (O. A.) ..	656	Anaphylactic Shock, Tatat (Nag) (H. P.) ..	298	Appendix, Carcinoid Tumour of the (Cruickshank) (H. P.) ..	92
Adhesions, Thoracoscopic Examination and Cauterization of (Benjamin) (O. A.) ..	212	Anaphylaxis, Insulin (Bose) (O. A.) ..	465	<i>Appleton-Century Co. Published by—The Practitioners' Library of Medicine and Surgery, Volume XI</i> ..	511
Adrenal Cortical Extract in Cholera (Dutta) (C.) ..	263	Anderson, R. G. The Problem of the Enlarged Heart in General Practice (C. T.) ..	564	— <i>Co. Published by—The Practitioners' Library of Medicine and Surgery, Volume XII</i> ..	705
Ahmed, H. Hæmatemesis in a Case of Malaria (H. P.) ..	486	Andreasen, A. T. Head Injuries: A Clinical Lecture (S. A.) ..	552	Arsenic in Human Tissues and Excreta (Bagchi and Ganguly) (O. A.) ..	477
'Albuminuria' or Proteinuria (Harrison) (C. T.) ..	39	Aneurism, Dissecting—Report of a Case (Carruthers) (H. P.) ..	484	Arsphenamine, The Choice of Bismuth or Mercury with (Cannon and Robertson) (C. T.) ..	505
Allahabad, A Case of Tick Typhus at (Banerji) (H. P.) ..	297	Angina Pectoris, A Syncope Form of (An Electrocardiographical Study) (Gupta) (O. A.) ..	295	Artificial Pneumothorax Containing a small quantity of Gas, Determination of the (Schill) (C. T.) ..	252
Allen, F. M. B. <i>Aids to Diagnosis and Treatment of Diseases of Children</i> ..	382	<i>Anopheles ludlowi</i> Invasion of Bengal by Years (A map) (Senior White) (S. A.) ..	314	—Pneumothorax Treatment in 1,039 Patients, An Analysis of (Frimodt-Møller and Verghese) (O. A.) ..	208
Allergy (Dharmendra) (S. A.) ..	166	— <i>stephensi</i> Liston, 1901, Races of (Sweet and Rao) (O. A.) ..	665		
All-India Medical Conference, 1936, Karachi, The XIII (M. N.) ..	176	— <i>sundaicus</i> ('ludlowi') on the Chilka Lake, The Presence of (Senior White) (O. A.) ..	361		
—Medical Conference, XIV, Madras, 1937 (M. N.) ..	693	— <i>sundaicus</i> (former name <i>ludlowi</i>), Invasion of Lower Bengal (Senior White) (S. A.) ..	307		
—Ophthalmological Society's Fifth Conference (M. N.) ..	436	Antigen Emulsion in the Kahn Test, An Apparatus for the Distribution of (Seshadrinathan and Timothy) (O. A.) ..	21		
Ames, A. <i>see</i> Hoxworth, P. Blood Grouping and Compatibility: A Simple Technique for Determination from Small Amounts of Defibrinated Whole Blood (C. T.) ..	696	Antigens of Bacteria, The Immunizing (C. T.) ..	634		
Amœbiasis, Intestinal, Chronic, Yatren in Infection with Indian Strains of <i>E. histolytica</i> (Chopra, Sen and Gupta) (O. A.) ..	348	Antimalarial Drugs, Synthetic, Individual Variations in the Effectiveness of (Chopra, Sen and Roy) (O. A.) ..	131		
Amœbic Dysentery in Chicago (C. T.) ..	637				
Anæmia, The Development of Acute Hæmolytic, during Administration of Sulfanilic Acid (Harvey and Janeway) (C. T.) ..	697				

	Page		Page		Page
Asthma: Immunological Mechanism, Diagnosis and Treatment, with Special Reference to Vaccine Therapy (Harley) (C. T.) ..	119	Bankart, A. S. B. The Use and Abuse of Manipulative Surgery (C. T.) ..	45	Blood Grouping and Compatibility: A Simple Technique for Determination from Small Amounts of Defibrinated Whole Blood (Hoxworth and other) (C. T.) ..	690
— The Treatment of (Wilson) (C. T.) ..	107	Basu, R. K. Stone in the Urethra of a Baby (H. P.) ..	94	— Pressure, Systemic. The Relation of, to Intra-Ocular Pressure (Jaswal) (O. A.) ..	602
Atebrin and Atebrin-Plasmochin Combination on Indian Strains of Malaria, A Comparative Study of the Action of (Chopra, Hayter and Sen) (O. A.) ..	458	— U. P. Treatment of Tuberculous Hæmoptysis by Subcutaneous Emphysema (O. A.) ..	241	— Stored Cadaver. The Transfusion of (Shamov) (C. T.) ..	753
— Musonate, Treatment of Malaria in Children with (De) (O. A.) ..	290	Bates, R. The Treatment of Actinomycosis (C. T.) ..	636	— Transfusion Service in a District Hospital, Organization of a (Dutta) (O. A.) ..	715
— Plasmochin Combination, A Comparative Study of the Action of Atebrin and, on Indian Strains of Malaria, Part II (Chopra, Hayter and Sen) (O. A.) ..	458	Bcaumont, G. E. <i>Medicine; Essentials for Practitioners and Students</i> ..	758	Blundell, R. H., and other. <i>Trial of Buck Ruxton</i> ..	642
— and Plasmochin: Malaria and its Treatment by the Synthetic Remedies (Nayudu) (O. A.) ..	531	Bed Bugs and of Their Eggs, The Effect of Reduced Pressure Combined with Increased Temperature on the Viability of (Somasekhar) (O. A.) ..	734	Bombay Medical Council (M. N.) ..	316
Attic, Acute Inflammation of the— Its Diagnosis and Treatment (Rashid) (O. A.) ..	410	Bengal Pharmaceutical Association, Presidential Address to (Chopra) (M. N.) ..	101	Bone, The Giant-cell Tumour of (Hariharan) (O. A.) ..	151
Auricular Fibrillation, A Study of Thirty-nine Cases of (Raman) (O. A.) ..	473	Bengali Diets, Cooked, The Protein and Mineral Values of Some (Guha) (O. A.) ..	24	Bordia, N. (With a Note by J. R. J. Tyrrell.) Oxygenation of the Peritoneal Cavity in the Treatment of Tuberculosis of the Abdomen (O. A.) ..	233
Aykroyd, W. R., and Krishnan, B. G. Diet Surveys in South Indian Villages (C. T.) ..	372	Benjamin, P. V. Thoracoplasty in Pulmonary and Pleural Tuberculosis (O. A.) ..	227	Bose, J. P. Insulin Anaphylaxis (O. A.) ..	465
— W. R., and Krishnan, B. G. Stomatitis Due to Vitamin-B ₂ Deficiency (C. T.) ..	179	— P. V. Thoracoscopic Examination and Cauterization of Adhesions (O. A.) ..	212	Bourne, A. W. <i>Synopsis of Obstetrics and Gynecology</i> ..	577
— W. R., and Rajagopal, K. The State of Nutrition of School Children in South India (C. T.) ..	178	Bentley, F. J. <i>Artificial Pneumothorax: Experience of the London County Council</i> ..	257	Brahdy, L., and Kahn, S. <i>Trauma and Disease</i> ..	512
B		Benzedrine (C. T.) ..	637	Bram, I. <i>Exophthalmic Goiter and its Medical Treatment</i> ..	258
B. C. G. Vaccine against Tuberculosis in Children, The Use of (Kereszturi and Park) (C. T.) ..	254	Beriberi, Electrocardiographic Changes in (Raman) (O. A.) ..	717	Brash, J. C., and other. <i>Cunningham's Textbook of Anatomy</i> ..	513
Baby, Stone in the Urethra of a (Basu) (H. P.) ..	94	Berkeley-Hill, O. A. Case of Cataplexy (H. P.) ..	614	Bray, G. W. <i>Recent Advances in Allergy (Asthma, Hay Fever, Eczema, Migraine, etc.)</i> ..	119
Bacillary Dysentery, A Case of Cancerum Oris as a Complication of (Ghose) (H. P.) ..	419	Best, C. H., and other. <i>The Physiological Basis of Medical Practice, etc.</i> ..	443	Brook, S. <i>The Basis of Clinical Neurology, etc.</i> ..	760
Bacteria, The Immunizing Antigens of (C. T.) ..	634	Bhaduri, N. V., see Maplestone, P. A. Gnathostomiasis in Human Beings (O. A.) ..	713	Brown, E. L. <i>Nursing as a Profession</i> ..	448
Bacterial Infections, Chemotherapy in (E.) ..	487	Bhattacharya, M., see Sarkar, S. L. The Effects of the Injections of Milk Preparations in Leprosy (O. A.) ..	398	— E. L. <i>Physicians and Medical Care</i> ..	578
Bacteriophages, Commercial, Study of (Pasricha, Lahiri, Gupta and Chatterjee) (O. A.) ..	659	— S. N., see Chopra, R. N., and Hayter, R. T. M. Radiological Laboratory Investigations of Chronic Gastro-Intestinal Disturbances in the Tropics (O. A.) ..	129	— W. <i>Mind, Medicine and Metaphysics: The Philosophy of a Physician</i> ..	185
Bacterium pseudo-carolinus Infection of the Bladder (Sharma) (H. P.) ..	549	Biggar, J. Sex Education (S. A.) ..	744	Brucella abortus Infection in Aden, A Note on a Case of (Phipson) (O. A.) ..	656
Bagchi, K. N. Significance of Florence Test for Seminal Stains (O. A.) ..	90	Bigger, J. W. <i>Handbook of Hygiene for Students and Practitioners of Medicine</i> ..	385	Buchanan's <i>Manual of Anatomy including Embryology</i> ..	513
— K. N., and Ganguly, H. D. Arsenic in Human Tissues and Excreta (O. A.) ..	477	Bilateral Pneumothorax and Pregnancy (Schill) (C. T.) ..	255	Buckley, C. W. <i>Chronic Rheumatic Diseases</i> ..	642
Bagot, R. A. <i>Nursing</i> ..	576	Bismuth or Mercury with Arsphenamine (Cannon and Robertson) (C. T.) ..	505	Bugs, Bed, and Their Eggs, The Effect of Reduced Pressure Combined with Increased Temperature on the Viability of (Somasekhar) (O. A.) ..	734
Bailey, H. <i>Diseases of the Testicle</i> ..	382	Bisulphite-Binding Power of the Blood in Cases of Epidemic Dropsy, Anaemia and Malaria and its possible bearing on a Vitamin-B Deficiency (Wilson and Ghosh) (O. A.) ..	147	Burns, B. H., and other. <i>Recent Advances in Orthopaedic Surgery</i> ..	704
— H., and other. <i>Recent Advances in Genito-Urinary Surgery</i> ..	442	Bladder, Bacterium pseudo-carolinus Infection of the (Sharma) (H. P.) ..	549	Burns, The Use of Tea in the Treatment of (Peiris) (O. A.) ..	718
Bajaj, N. L. A Melanotic Sarcoma of the Anal Region (H. P.) ..	29	— Multiple Stones in the (Khusr) (H. P.) ..	28	Burrell, L. S. T. <i>Recent Advances in Pulmonary Tuberculosis</i> ..	638
Banerjee, J. C. Some Observations on Chrysotherapy in Pulmonary Tuberculosis (O. A.) ..	205	Blood, The Bisulphite-Binding Power of the, in Cases of Epidemic Dropsy, Anaemia and Malaria and its possible bearing on a Vitamin-B Deficiency (Wilson and Ghosh) (O. A.) ..	147	Butler, H. M. <i>Blood Cultures and Their Significance</i> ..	703
Banerji, N. D. A Case of Syndactylism (C. T.) ..	680			C	
— N. D. Epidemic Dropsy in Cawnpore (O. A.) ..	675			Cabot, H. Edited by— <i>Modern Urology, Volumes I and II</i> ..	320
— R. N. A Case of Tick Typhus at Allahabad (H. P.) ..	297			Calcium, Chemistry of, in Tuberculosis (Sen) (O. A.) ..	598
				— Oxalate Calculus in the Urethra (Mittra) (H. P.) ..	94

ELECTROCARDIOGRAPHIC CHANGES IN EPIDEMIC DROPSY

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.),
M.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

Honorary Physician to H. M. The King

R. N. CHAUDHURI, M.B.

and

N. DE, M.B.

(From the Department of Pharmacology, School of
Tropical Medicine, Calcutta)

THE condition of the heart in epidemic dropsy has received considerable attention from clinicians during the last decade. A perusal of the large amount of literature which has accumulated on the subject shows that the studies were chiefly limited to investigations of the subjective and objective manifestations in the patient. Little attention has so far been paid to a systematic investigation of the electrocardiographic changes. As it has been definitely shown that electrical changes in the heart give early and reliable evidence of cardiac damage, electrocardiography, as a routine investigation in all cases of epidemic dropsy admitted to the Carmichael Hospital for Tropical Diseases, was instituted. The following observations are based on a study of the electrocardiograms of 50 such cases. Patients who gave a history of previous cardiac disease or who showed old-standing organic lesions were excluded from this group.

Analysis of cases

I. Rate of the heart.—There was some degree of tachycardia in about 90 per cent of cases. A slight degree of tachycardia (heart rate between 81 and 99) was observed in 15 cases, moderate tachycardia (rate between 100 and 115) in 21 cases and severe tachycardia (rate of 120 or more) in nine cases. The highest rate of heart beat recorded in this series was 136 per minute. In only five patients was the pulse rate 80 or below.

II. Rhythm.—The rhythm was practically regular in 42 cases. A moderate degree of sinus irregularity was observed in five patients. In this condition the rhythm varied in regular cycles and each cycle showed a progressive lengthening of the interval between beats followed by a progressive shortening. The P—R interval remained constant while the T—P interval showed variation in length. In two patients the regular rhythm was interrupted by the occurrence of extra systoles, auricular in one case, and nodal in the other. In one patient, auricular fibrillation with a moderate degree of tachycardia was observed.

III. P wave (the auricular deflection).—The normal characters of the P wave are as follows :—

Height in largest lead—1 to 2 mm.; direction in leads I and II—upward; direction in lead III—upward, diphasic or downward; form—rounded, may be notched; duration—not more than 0.1 second. In the records where one lead is biphasic or iso-electric and the amplitude in other leads about equal, the normal values for P vary from 0.9 mm. to 1.8 mm.

In the present series of patients, the height of the P wave was within normal limits in 38 cases. In three patients it was below normal, indicating a poor functional condition of the auricular muscle or a poor state of nutrition; in eight patients the voltage was above normal, indicating a hypertrophy or an overactivity of the auricles. The direction of the P wave was upright in the first two leads in all cases except in the case where there was auricular fibrillation. The P wave, in the third lead, was iso-electric in three cases and inverted in three cases. The duration of P was within normal limits in 49 out of 50 cases, the remaining one being a case of auricular fibrillation. In four cases, a notching of the P wave was noticeable. This is probably not to be considered pathological as, according to Pardee (1933), notching may be a normal variation of the P wave. The opinion of Pardee on this point may be cited in this connection : 'The normal P is composed of overlapping of two electrical effects, one of which is due to each auricle. In the majority they fall so close to each other that no notching occurs. Occasionally the path of contraction in one auricle from the sino-auricular node to the tip of the apex or the base of the auricle may be larger than usual, so that the potential on that side will be slightly delayed in reaching its height. Thus, the peaks of the two electrical effects might not coincide closely, and a notching of P results'.

IV. P—R interval (auriculo-ventricular conduction time).—The normal limits of this interval are from 0.12 second to 0.2 second.

In 29 patients, the P—R interval was within normal limits. In 20 patients, it was found to be 0.10 second, i.e., below normal. In the remaining case, the P—R interval was 0.12 second in the first record but was changed to 0.10 second in the second record. The change in rate was but slight, 125 to 130 per minute in this case, and there was evidence of a nodal extra-systole.

V. Q R S waves (initial ventricular deflection).—A summary of the limits of normal Q R S is given below :—

Height in the largest lead—7 to 17 mm.; direction in leads I, II and III—chiefly upward (R), either Q or S may be present singly, but neither as large as R; form—one, two or three sharply pointed peaks or vibratory groups;

duration—not more than 0.1 second. If the record in one lead is diphasic, the amplitude in the other two leads is about equal; normal values of the height of Q R S may vary from 6 mm. to 15 mm.

Judged by the above standards, the height of Q R S, in the leads showing the maximum excursion, was normal in 32 cases. It was less than normal in two cases, one of which was a case of auricular fibrillation. This low voltage (associated in these two cases with a maximum voltage of T less than normal) indicates a weak physiological activity of the ventricles. In 15 cases the height of Q R S was above normal limits. This, in the absence of bundle branch block or abnormal degree of notching, would signify a physiological hyperactivity of muscle. In one case, the voltage was normal in the first tracing and was higher than normal in the second taken after a few days of treatment.

The direction of Q R S in the different leads was normal in 42 cases. In three cases, there was right ventricular preponderance, as indicated by the initial ventricular complex being directed chiefly downward in lead I and upward in lead III.

VI. S—T segment.—This was normal (iso-electric or very slightly above or below the iso-electric line) in 48 cases. Coronary T wave was seen in two cases. The characteristic feature of coronary T wave, according to Pardee, is an upward convexity of the S—T segment which carries the record at first slightly above the point of origin and then downward to form an inverted T wave. It indicates a localized myocardial degenerative process which is no longer in an acute stage.

VII. T wave (the terminal ventricular deflection).—The characteristics of the normal T wave are :—

Height in the largest lead—1.5 to 5 mm.; direction in leads I and II—upward; direction in lead III—upward, biphasic or downward; form—peaked. In those electrocardiograms where one lead is biphasic or iso-electric the height of T in the lead where it shows maximum excursion varies from 1.3 mm. to 4.5 mm.

The height of T was found to be within normal limits in 38 cases, and in 12 cases it was below normal. This may be due to (i) poor state of myocardial nutrition, (ii) decreased strength of ventricular contraction, or (iii) diffuse disease of the myocardium.

The direction of the T wave was upward in all leads in 21 cases. T_1 was iso-electric in one case and biphasic in one case. T_2 and T_3 were inverted in one case; T_2 and T_3 were iso-electric in one case; T_2 iso-electric with T_3 inverted in one case; T_2 biphasic with T_3 inverted in one case and T_2 biphasic in one case. Associated with upright T in the other two leads inversion of T_3 was present in 13 cases, a biphasic T_3 in one case and an iso-electric T_3 in seven cases.

In one patient, T_3 was biphasic in the first tracing but inverted in the later records.

The form of the T wave was normal in all the cases in which it was upright.

Discussion.—From an analysis of the data at our disposal, we are forced to the conclusion that a functional derangement of the heart is the most common feature in epidemic dropsy. Tachycardia of a moderate degree is common and is usually associated with a shortening of the T—P interval. An interesting finding, present in nearly 40 per cent of the cases, is an abnormally short P—R interval (0.1 second only). This abnormally short P—R interval does not seem to be dependent on the rate of the heart, as it has been found associated with a heart rate of 70 as well as with a heart rate of 136. An abnormally short P—R interval is generally considered characteristic of nodal rhythm (nodal rhythm type I of Cowan and Ritchie, 1935) with a slow rate or nodal tachycardia with a rapid heart rate. Electrocardiographic changes of this type are typical of nodal rhythm but there are a few points which have to be considered before a final opinion can be offered. The P wave is usually found to be inverted in nodal rhythm; in the cases under consideration, the P wave is upright in the first two leads. In three out of the 20 cases with an abnormally short P—R interval, there was definite sinus arrhythmia. Sinus arrhythmia is very seldom associated with nodal rhythm. This fact, taken in conjunction with the contour and direction of the P wave, makes it difficult for us to conclude that the cases are genuine cases of nodal rhythm. The P wave is probably originating from the S—A node. One school of cardiologists thinks that a P wave, which is upright in the first two leads and precedes the Q R S complex, has its origin at the A—V node. As this is a debatable point, we will leave it as an open question.

It will thus be seen that epidemic dropsy produces sinus tachycardia. The rhythm has been found to be generally regular. The occurrence of extra-systoles (auricular in one, and nodal in another) supports the supposition that in epidemic dropsy there is increased excitability of parts of the heart other than the sino-auricular node. As regards auricular activity, this is found to be normal in most cases (38 out of 50). In three cases (6 per cent) the height of the P wave is above normal limits, indicating an increase in the muscular activity of the auricles, and in three cases a subnormal height of P indicates depressed activity. It is probable that, in the case where this height of P is above normal limits, there is an enlargement (dilatation with hypertrophy) of the auricles.

Ventricular activity as judged from the height and contour of Q R S is normal in 32 out of 50 cases. But in 15 cases (30 per cent) the higher voltage points to an increase in the

irritability of the muscle. Enlargement of the heart is frequently seen in epidemic dropsy, as has been already pointed out by Chopra and Basu (1930).

That organic changes, most probably of the nature of degeneration, may be produced in the heart by epidemic dropsy, is seen from the occurrence of auricular fibrillation in one case and the 'coronary T wave' in two cases. Abnormalities of the T wave, especially in the leads I and II and in the voltage of largest T, are suggestive of myocardial damage due possibly to accumulation of fluid between the individual fibres.

In 12 cases the height of the largest T wave was found to be abnormally small. In two cases this low voltage of T was associated with Q R S of abnormally low voltage, indicating a weak functional activity of the ventricles. Of the remaining 10 cases, one was associated with Q R S of abnormal height and the rest were associated with Q R S of normal height. Roughly speaking, the voltage of T is normally about 1/5 to 1/4 that of R, and ranges from 0.2 to 0.5 millivolt. In all the leads the T wave follows the amplitude changes of R. When these relations do not obtain, a suspicion of myocardial derangement exists. This change is not severe enough to incapacitate the patient seriously but it is rare to find a small T wave with large Q R S excursion from a heart with normal reserve power.

Summary

(1) A critical study of electrocardiograms taken in a series of 50 inpatients of the Carmichael Hospital for Tropical Diseases suffering from epidemic dropsy is reported.

(2) In epidemic dropsy, functional disorder of the heart is very common. Sinus tachycardia and sinus arrhythmia are frequently met with. Extra-systoles sometimes occur.

(3) The P—R interval is found abnormally short in a fair proportion of cases.

(4) There is evidence of increased auricular activity in a very small proportion of the cases, which probably indicates enlargement of the auricles.

(5) The occurrence of auricular fibrillation, coronary T wave and other abnormalities of the T wave are suggestive of myocardial damage, probably degeneration.

CLINICAL STUDY OF SIXTY-THREE CASES OF ORIENTAL SORE

By J. GOODALL

CAPTAIN, I.M.S.

Chittagong

OWING to the earthquake which took place in Quetta on 30th May, 1935, it was found necessary to send two companies of K. G. O. (Bengal) Sappers and Miners to the scene of the catastrophe. These men were employed in work of salvage, and removal of dead and wounded. There were about five hundred and fifty men, and three or four officers, all of whom were physically fit at the time of arrival in the area. The vast majority of these men set off from Roorkee, in the United Provinces, on 1st June, 1935, and returned in November of the same year. They were a mixed collection of men, some Sikhs, some Hindus and some Mohammedans, with a few European sergeants and officers.

They provided the writer, after their return, with an excellent opportunity of studying the course, treatment, and general clinical picture of oriental sore. Approximately 11.8 per cent of them including one European sergeant and one officer developed sores in Quetta or at varying periods afterwards, on arrival back in Roorkee. Their average age was twenty-six years. Practically all the men said that the flies had been numerous and they had been bitten badly on their faces, arms, and legs. The more educated remarked that 'the ones which bit were sandflies'.

Symptoms

The sores appeared first as small red papules which gradually increased in size and finally, after a varying period of months, turned bluish in colour, softened in the centre, broke down and ulcerated. There was no associated pain, and no itchiness. In the case of the Indian troops, the majority of these sores became secondarily infected. They thought nothing of rubbing grass, leaves, or cowdung into their sores as soon as they were out of hospital. When this occurred the sores became painful, the surrounding tissues much swollen and pus formed.

The number of sores on one man varied from one to seventeen, but single sores were uncommon and a typical case usually presented not less than three nor more than eight.

Laboratory examinations

Every case of suspected oriental sore was examined for *Leishmania tropica*. In the sixty-three cases treated thirty-six showed Leishman-Donovan bodies. These bodies were not always identical in shape; there was the round or oval thick type to which the majority belonged, and the flattened type, the ends of which were almost pointed. They were very numerous in

the large endothelial cells. In spite of careful study, no bodies were ever seen in peripheral blood films.

The specimens were obtained by undermining the margins of the sores with either an ordinary hypodermic needle, or a fine glass pipette, the point being directed towards the healthy tissue. It was very unusual to obtain positive results from tissue which was heavily secondarily infected. The most satisfactory from this point of view were the small early sores before they had broken down. As a rule these were literally swarming with leishmania. Leishman's stain was commonly used, but Giemsa's was also employed and found very satisfactory.

Blood.—This was fully examined in about fifteen cases. The red corpuscles were present in normal numbers and showed no abnormality. The hæmoglobin was normal.

The white corpuscles showed a constant slight increase, eight to eleven thousand per c.mm.

The differential counts revealed in every case an eosinophilia, of from four to fourteen per cent. There was an increase in the number of small lymphocytes on an average of 6 per cent. The large lymphocytes and monocytes, counted together, on an average were 8 per cent above the normal, a typical count being as follows :—

Polymorphonuclears (neutrophil) ..	50
Small lymphocytes ..	23
Large lymphocytes and monocytes ..	17
Polymorphonuclears (eosinophil) ..	10

The aldehyde test was carried out on six cases with a negative result.

Wassermann reaction carried out on two very chronic cases was negative.

Treatment

As numbers of cases of oriental sore began to appear at the Indian Military Hospital, Roorkee, for treatment, and as the sores did not improve at once, records of the different drugs used were kept for comparison. The number of patients soon became so large that special days and times had to be allotted for their attendance and careful notes kept of each case. It must be made clear, however, that no startling results nor rapid cures have been obtained. The following records of treatment are offered as showing the effects of the different drugs, antimony, emetine and orisol, on patients of the same type, and infected under the same conditions. It is, in other words, a fair test of the respective merits of these drugs.

Neostibosan was also used but only in one case, for reasons of economy.

The treatment consisted of two distinct kinds :—

(a) Specific treatment and (b) local treatment, the two always being administered in conjunction with each other. At first potassium antimony tartrate alone was used. Later,

emetine, orisol and finally neostibosan were tried. Reference was made to the reports of Varmā (1927) and Dās Gupta (1930) and the original technique was altered slightly to comply with their methods. This made no material difference to the results obtained.

Local treatment

The majority of cases were treated with dressings of gauze soaked in normal saline, the wound having been previously cleaned with spirit. Finally, a bandage was applied. This dressing was changed twice a day, outdoor patients attending in the morning and evening. Septic cases were sometimes fomented with magnesium sulphate or boric acid. At times the dressings were soaked in hypertonic saline but this made no appreciable difference. Iodine was painted over the healing areas in several cases and was found very successful, but this was only used when definite signs of healing had been seen.

Specific treatment

Potassium antimony tartrate.—This was used in varying strengths which can be seen on reference to the table. For a soldier of average weight and in good health, apart from the sores, the most effective dosage was as follows: A preliminary dose of gr. $\frac{1}{2}$ potassium antimony tartrate in 5 c.cm. sterile freshly-prepared distilled water was given intravenously, and this was followed three days later by a dose of gr. 1 in 5 c.cm. of the same solvent. Thereafter twice-weekly doses of gr. $1\frac{1}{2}$ were injected until the end of a month, when the patient was given a rest for one week. Then the injections were resumed until definite signs of healing were well established. Local treatment was rigidly carried out throughout.

At one time gr. 2 of potassium antimony tartrate were given twice weekly, but this produced

EXPLANATION OF PLATE I

Fig. 1.—Case 7 (see table). Photograph taken four weeks after commencement of treatment. Sores were secondarily infected and the treatment lasted ninety days before a cure resulted. Patient frequently interfered with his treatment and rubbed filth into his sores. Treatment consisted of sixteen injections of potassium antimony tartrate and three of emetine with local application of normal saline.

Fig. 2.—Same case one month later.

Fig. 3.—Condition on discharge.

Fig. 4.—Early untreated case of oriental sore. Note the spread-out nature of the lesions which are not so typical as the lesions shown in the other photographs.

Fig. 5.—Case 29. Photograph taken three weeks after commencement of treatment. Shows two sores—one on face and one wrist. This case which was positive for *Leishmania tropica* was cured after two months' treatment with antimony and orisol.

Fig. 6.—Case 40. Photograph taken 14 days after commencement of treatment. Shows two lesions—one on face and one on wrist. The one on the face is a typical early sore. It was found to contain numerous *Leishmania tropica* (see table).

toxic symptoms, i.e., coughing, burning sensation in the throat, nausea and vomiting. Two men actually coughed up a little blood. Thus, although this treatment did seem to hasten the rate of healing, it was too dangerous to continue. The men were always excused duty on the days on which they attended for treatment.

The time taken for cases to heal varied tremendously. Some healed up rapidly after three or four grains with the addition of the local treatment, others required more than eighteen grains. The chronic cases were all secondarily infected. The first signs of healing were usually a drying up of the moist lesion followed by the formation of a hard crust which later peeled off leaving a white scaly and often itchy area. In addition the removal of the crust usually left a hollow behind and the ulcers eventually healed leaving marked scarring. Several men among the number sent to Quetta had suffered from oriental sore before but none of these became infected a second time.

Emetine hydrochloride.—Only one cure was obtained by using this drug alone in conjunction with local treatment. A reference to the table will show that twenty cases were treated with it, but, although some improvement was noted at the time, this improvement was only temporary.

The usual dosage was gr. $\frac{1}{2}$ emetine hydrochloride in 3 c.cm. sterile distilled water for one large sore. This was repeated once a week. Some patients were given as much as gr. 2 at a time according to the number of sores treated. The drug was administered by injection into the edge of the sores and the surrounding tissues, the first signs of healing being the creeping in of the ulcer margin. Many cases, however, showed a false improvement. The margin of apparently healthy tissue crept in but later on turned a bluish colour, softened and ulcerated again. It was noted in treating cases with emetine that, unless the limb on which the ulcer being treated was placed on a firm support, the patient was apt suddenly to move it, jerking the needle out, so that a stream of emetine was directed upwards, more often than not into the doctor's eye. This resulted later in a painful conjunctivitis. Used in conjunction with antimony in certain chronic cases it gave good results, but was of very little use by itself.

Orisol.—This was used in twenty cases. On the whole the results were disappointing. Four cases were cured by this treatment alone in addition to local treatment. The minimum amount required was 5 c.cm. to cure two sores.

The dosage used was 1 c.cm. to 3 c.cm. per sore according to the size. It was a satisfactory form of treatment for single or small sores, but difficult and expensive in cases of multiple sores. Injections were made into the margins of the sores in four places so as to cover and infiltrate

the whole area. A few cases showed a rapid improvement by drying up and forming a scab which, when it fell off, left a healed area. Other cases, the majority, showed no appreciable change. The patients complained of pain at the time of injection but this soon disappeared.

Neostibosan.—Owing to the cost of this drug only one case was treated with it. He was given nine intravenous injections of gr. 0.3 neostibosan on consecutive days. In addition his sores, nine in number, were dressed with normal saline changed twice daily. He improved so much at the end of his course that he was allowed to leave hospital and attend for dressings. In the table are given details of the cases treated.

Conclusions

1. Antimony in either its trivalent or pentavalent form is still the most effective and cheapest drug in the treatment of oriental sores.

The dose of potassium antimony tartrate should be regulated according to the weight of the patient and in any case should never exceed gr. 2 at one time. It must be carefully injected owing to the sloughing it causes if allowed to escape into the tissues. This is a severe drawback when one has to deal with large numbers of patients. One badly-injected dose causes so much pain to a patient that soon all hear of it and are apt to be nervous lest they too suffer in the same way.

In Roorkee with sometimes fifty men being treated at once there were three sloughs in the arm, during the whole period of treatment. If an accident has occurred and the arm is painful, then iodex is a useful application and gives some relief.

Neostibosan is expensive but is not so liable to cause sore arms or sloughing.

2. In chronic cases emetine hydrochloride gr. $\frac{1}{2}$ to gr. 1 injected into the margins of the sores hastens the healing process produced by the antimony. This treatment is however rather painful.

3. Orisol (berberine), generally speaking, was not as successful as one might expect from the results claimed for it. For single sores or small lesions, before they have broken down, this drug gives good results. This latter conclusion was also arrived at by Napier (Knowles, 1934) some

EXPLANATION OF PLATE II

Fig. 7.—Case 8. Photograph taken three weeks after date of commencement of treatment. Was discharged as cured after two months' treatment with potassium antimony tartrate and local dressings of saline, iodine, and boric acid.

Figs. 8 and 9 show close-up views of left and right hand and wrist of same case three weeks later.

Fig. 10.—Same case showing condition on discharge. Note the severe scarring which remains and a certain degree of pitting.

62	22	5 "	2	+	2	85	10	9½	"	Still under treatment.
63	24	1 month	13	—	6	24	5	4½	"	Still under treatment.

* Sores developed in Quetta, therefore incubation period is unknown.

years ago. Results with large or multiple sores are almost always disappointing.

4. Local dressings play a very important part in the rapidity of cure. There were many examples of patients who kept their dressings and sores clean which consequently healed up in from three to six weeks. There were many examples of others who were careless or ignorant and allowed their sores to become secondarily infected. They then took even as long as four months to cure.

Normal saline is a very satisfactory dressing, followed by iodine once healing has started.

5. Early treatment is most essential. The old-standing case is hard to cure: the recently developed case is comparatively easy to cure.

6. The total dosage of antimony required to effect a cure was less than is usually stated, due to the supplementary emetine or orisol and rigid local treatment.

[Note.—There are surprisingly few clinical records—of a series of any significant size—of cases of oriental sore; we therefore welcome this contribution. There are a few points that seem to us to be of special interest.

Incubation period.—Circumstances made it possible to demarcate the minimum incubation

that the incubation period is quite frequently much longer than four months (Napier and Halder, 1936), yet the general impression on this subject is that it is *usually* shorter than

Fig. 12.—Leishmania —.

three months; this series indicates that this is not the case.

Distribution.—The spot maps shown here were kindly prepared by Captain Goodall at our suggestion. They bring out three points.

Fig. 11.—Leishmania +.

period. In 35 (or 56 per cent) it was three months or more, and in 12 (or 19 per cent) it was four months or more. Though it is known

Fig. 13.—One or two sores only.

They confirm the observation, first emphasized by Acton (1919), that the sores occur on parts of the body most exposed to sandfly bites.

The distribution is much the same in those cases in which there are one or two sores and in those in which there are multiple sores. This suggests that the ætiology of the initial sore is the same as that of the other sores; that is, it negatives, in these cases, any suggestion that the infection has spread by the blood or the lymphatics.

Finally, as the distribution is practically the same in those cases in which leishmania was found and those in which it was not found, it seems probable that the latter group were true cases of oriental sore in which the parasites were scanty.

Treatment.—On the whole, the results of treatment seem to have been satisfactory. In 51 cases a cure was effected in an average period of about one and three-quarter months; in three others the sores reappeared; and in nine

Fig. 14.—Multiple sores.

instances the results of treatment are not known.

From the point of view of appraising the value of the forms of treatment used, it is a pity that so much mixing of the different forms of treatment in the same individual had to be done, but research had to be sacrificed to utility, as the writer's primary objective was naturally to get the men back to duty as quickly as possible.

Of the 14 cases in which potassium antimony tartrate alone was given, the average duration of treatment was 48 days, but two of these relapsed. Of 16 cases in which more than one emetine injection was given in addition to the potassium antimony tartrate the average duration of the treatment was 60 days, but no relapses occurred; it is probable that in these cases

(Continued at foot of next column)

THE CLINICAL ASPECT OF PLACENTA PRÆVIA AND ITS MANAGEMENT IN INDIAN CONDITIONS*

By J. CHAKRAVERTI, M.B. (Cal.), M.C.O.G.

Associate Professor of Obstetrics and Gynaecology, Carmichael Medical College, Calcutta; Visiting Surgeon, Chittaranjan Seva Sadan, Calcutta; Honorary Visiting Gynaecologist, General Hospitals, Howrah, Calcutta

A PLACENTA is called 'prævia' when it is attached partly or wholly to the dilating zone of the uterus, viz, in the lower uterine segment. The condition produced goes by the name of 'unavoidable hæmorrhage' as the bleeding is inevitable. The condition has been known in the literature since the time of Hippocrates (de Lee, 1928) when it was thought to be prolapse of the normally-situated placenta. It forms one of the grave obstetrical complications as it constitutes the commonest important cause of antepartum hæmorrhage in the later months of pregnancy.

Incidence:—It is difficult to state correctly the incidence of this condition in India. The following table shows the number of cases in

* Being a paper read at the First All-India Congress of Obstetricians held in Madras in January last.

(Continued from previous column)

emetine was given because the response to the antimony treatment was slow. In the one case in which emetine alone was used the result was undetermined. In three cases in which berberine sulphate alone was used the results were all satisfactory, but the duration of treatment was above the average.

We feel that the series has demonstrated the value of potassium antimony tartrate as the mainstay in the treatment of the disease; this is important in view of the very low cost of this substance. (The sodium salt is equally efficacious and cheap, and we have found it less toxic.) It also demonstrates that a judicious combination of intravenous antimony with some form of local treatment is probably the most effective way of treating the disease. The writer seems to favour emetine but there is little evidence in his table to support this preference, and we have always found berberine sulphate very effective for single sores.

The writer seems satisfied with the progress in the case in which he used neostibosan. Our experience has led us to suspect that the trivalent antimony compounds are as effective as the pentavalent, but much more work needs to be done to establish this fact; we should like to see a large series in which sodium antimony tartrate, neostibosan, and foudadin were used on different cases.

treatment is strongly contra-indicated in poor houses, in insanitary surroundings and also in cases of central placenta prævia.

The management can be dealt with according to the various methods at our disposal, but a better plan would be to consider the treatment according to the different clinical pictures the patients usually present.

For the convenience of treatment and according to the commonest conditions in which patients are found, the cases may generally be classified as follows :—

Group A.—When the patient is not in labour and the cervix is closed or just admits the tip of a finger in a multipara.

Group B.—When the patient is in labour or the cervix is dilated 2 fingers.

Group C.—Central—the placenta covers the whole of the internal os.

Group A

1. *In slight cases* (bleeding not exceeding 2 to 4 ounces)—*expectant treatment*—watchful expectancy with rest in bed and sedatives. Authorities differ in this line of treatment, once the diagnosis is established. In my opinion, a patient may be treated on these lines provided she is placed in a suitable environment, hospital or private house, where every possible arrangement has been made for emergency help. The signals of danger should be given to the nurse in writing and the armamentaria for the need of a case of placenta prævia should be kept ready. 'Expectant treatment is indicated in a case of an elderly primipara whose chance of becoming pregnant again is remote. It is contra-indicated in full-term pregnancy or when a patient is in labour and when the placenta covers the internal os, i.e., is central'.

2. *In moderate or severe cases*—*plugging*. This is the old Rotunda method prescribed for over a century (Eden and Holland, 1931).

Patients are often seen in the hospital that have been sent by private practitioners, as well as by other maternity homes under the City Corporation, after plugging which was performed in an improper and ineffective way. In order to be effective, this small but temporary life-saving operation in a case of placenta prævia must be done thoroughly and methodically. Plugging in a case of placenta prævia to be effective cannot be done without instruments of which only a few are necessary. It also requires good light, particularly in a private house, and an assistant to hold the legs. Plugging should be preceded by rupture of the membranes whenever possible and followed by application of a tight abdominal binder.

The patient should be catheterized every 8 to 12 hours. If no pain starts the plugs should be changed after 12 to 16 hours in the summer, 24 to 32 hours in the winter.

Group B

This is the commonest condition in which most of the placenta prævia cases are seen in India.

1. *If lateral (high placenta prævia)*.—Rupture the membranes and apply a tight abdominal binder. This is the ideal method of managing a case of placenta prævia with safety to the mother as well to the baby. In fact, this method contributes largely to lowering the mortality rate, but its application is limited only to this variety of case. Sometimes, rupture of the membranes has to be supplemented by forceps or craniotomy. Rupture of the membranes should never be done if the presentation is transverse.

2. *If marginal*.—Bleeding should be controlled by any one of the following methods and the remainder of the delivery left to nature, i.e., to be terminated slowly and spontaneously.

(a) *Pressure of half breech over the bleeding placental area*.—(i) In breech presentation—it is easy; a leg is to be brought down after rupturing the membranes. (ii) In head or transverse presentation (a) version, if possible external; otherwise bipolar followed by bringing down a leg. In the majority of cases, the head presents and external version is not possible and the cervix does not allow internal version—hence bipolar podalic version is the method of choice.

Bipolar podalic version (Braxton Hick's) is the old but efficient method of managing a case of placenta prævia. It can be performed anywhere and at any time and practically in all varieties of cases of placenta prævia, if the cervix admits only 2 fingers which in a case of multipara is not uncommon. The method requires only one assistant and practically no instruments, but some training on the part of the obstetrician is of immense value. After version a foot is brought down to the vulva, heel pointing upwards and traction is put on just sufficient to stop bleeding. No time should be lost to find out the upper or lower leg. Difficulties may be experienced, (i) in rupturing the membranes which are not always easy to reach in a case of placenta prævia, (ii) in turning the child if the legs are extended, (iii) in finding the leg (a mistake may be made with a hand), and (iv) the leg may slip from the hand near the internal os. These difficulties are to a certain extent caused by want of experience. During the efforts to overcome these difficulties, a patient in the hands of a young specialist may bleed profusely. In such an eventuality, it is advisable that the obstetrician should change his line of action. Plugging should be resorted to to stop bleeding and the patient treated for loss of blood; otherwise his firm determination is sure to cause disaster. This is the first part of the treatment which should be performed quickly but methodically. The remainder of the management should be left to nature and

Summary of table

Calcutta—Eden Hospital	.. 1.2 per cent
Carmichael Hospital	.. 1.2 " "
Chittaranjan Seva Sadan	.. 1.3 " "
Calcutta	Average .. 1.2 per cent
Madras	.. 0.6 " "
Bombay	.. 0.8 " "
Incidence in India	.. 0.83 " "
Incidence in the British Isles	1.1 " "
Incidence in America varies widely—about 1 in 200	

5 years in the big hospitals of Calcutta, Madras and Bombay.

Thus, it will be seen from the above that the incidence of this condition in India is about 1 in 100. But it will certainly be higher if private cases are considered along with those in hospitals because, in India, unlike other countries in Europe and America, a fairly large number of cases, particularly those belonging to conservative families, are treated in private houses.

Morbid anatomy.—Under normal conditions the placenta is attached to the body of the uterus, most commonly to the posterior wall and less frequently to the anterior and lateral walls. In the last situation, however, it considerably encroaches on the anterior and posterior walls. The rarest place is the fundus (de Lee, 1928).

Although it is customary to classify the condition clinically into (i) central, (ii) marginal and (iii) lateral, a good deal of confusion still exists as there is some difference of opinion about the definition of the marginal and lateral types. Better terms would be complete or central and incomplete or non-central. Even then, these terms are more or less relative to the dilatation of the cervix. For instance, a placenta prævia which is central in position in the early stage of labour becomes marginal at the end of the first stage. Hence it would be appropriate to define the types with reference to the condition of the cervix, *e.g.*, central with 2 fingers dilatation of the cervix, and so on.

Besides the abnormal anatomical position, the placenta in this condition is usually bigger than normal, occupying a larger surface area. Naturally, it is thinner than normal due to poor vascularity of the lower uterine segment. The insertion of the cord is very often marginal or velamentous (Williams, 1931). Frequently infarcts are seen on the surface and sometimes there is foetal anomaly, as may be seen from case 1.

Symptomatology.—Placenta prævia has but one cardinal symptom, *viz.* visible hæmorrhage, which may be slight, moderate or severe and even, in some cases, fatal. The bleeding is spontaneous, *i.e.*, 'causeless'. It is painless and comes on suddenly without any warning, usually in the third trimester of pregnancy. Fortunately, bleeding in the first instance is usually slight in amount but it recurs at intervals of a few days or weeks. After the first appearance of bleeding, the subsequent attacks are precipitated by the slightest movements, *e.g.*, jolting or jerking, as in motoring or the act of coitus. The hæmorrhage is usually severe in the case of central and least in the case of lateral variety. Rarely, a case of lateral placenta prævia may bleed severely whereas a central one bleeds only when there is considerable advance in labour. Probably it depends more on the elasticity and contractility of the

tissue to which the placenta is attached than merely on its anatomical position.

The condition is much more common in multipara than in primipara. The occurrence in relation to parity, multipara to primipara, is as follows:—

Calcutta	5 : 1
Madras	8 : 1
Bombay	8 : 1
<hr/>			
Average for India	6 : 1
<hr/>			
British Isles	5 : 1
America	10 : 1

The sources of the bleeding are mainly the utero-placental sinuses and, in rare instances, the villi which are traumatized by the examining fingers (Eden and Holland, 1931). The question may be asked, why does a placenta prævia bleed? The reason is obvious when the patient is in labour as the cervix is drawn up like a sleeve over the placenta which lies in front. But a satisfactory explanation cannot be given when bleeding starts say at 28 weeks or before labour. Probably at this stage of pregnancy, the lower uterine segment which begins to form stretches gradually and the mature and fully-formed placenta attached to this part cannot keep pace with it. Naturally it becomes separated from the uterine wall, leaving open some of the utero-placental sinuses. This leads to the question of the origin of the lower uterine segment, which is one of the unsolved and controversial points in obstetrics. Personally, I think it grows from the isthmus which has a separate origin, distinct anatomical and histological features and separate nerve and blood supplies. This has been definitely proved by Prof. Oskar Fraenkle of Vienna in the 9th Congress of the Obstetricians and Gynecologists of the British Empire at Birmingham in 1933. The other factor that keeps on the bleeding is the poverty of the musculature of the lower uterine segment in contrast with the body or upper uterine part. Normally the sinuses are closed only by the contraction of the muscular tissues which are deficient in the lower uterine segment.

Diagnosis.—The existence of placenta prævia is usually elicited by physical examinations—(a) abdominal, (b) vaginal; a definite diagnosis can only be made by *vaginal examination*. Before making a vaginal examination in a suspected case of placenta prævia the practitioner must be warned about two points which are of great practical importance: (i) *Rigid aseptic precautions*, as if one was going to perform a major operation. This applies both to the maternal parts as well as to the examining hands. (ii) Some suitable packing material such as sterile gauze or cotton should be kept ready by the side of the examiner. This may

be necessary to control the bleeding, which usually takes places immediately after the examination, particularly in a private house and in a patient who has already been exsanguinated.

Recently, radiographic diagnosis of placenta prævia has been successfully performed by Francis Burke (1934 and 1935). Amniography was done after injecting the amniotic sac through the abdominal wall, with some radio-opaque substances, *e.g.*, uroselectan, or strontium iodide. The filling defect of the gestation sac shows the position of the placenta in the uterus. This is a distinct advance in the scientific methods of diagnosing a suspected case of placenta prævia before bleeding starts.

The diagnosis is to be made from other conditions which give rise to antepartum hæmorrhage, of which the most important is accidental hæmorrhage or ablatio placenta. This condition is always associated with pain in the abdomen and a certain amount of shock. The blood is more or less mixed with dark clots. The uterus is tender and board-like to the touch. The condition is often accompanied by the presence of albumin in the urine. The foetal heart sound disappears early.

It would be a wise principle to observe that, even in the absence of a positive finding, a painless and 'causeless' bleeding in a woman at the third trimester of pregnancy should be considered as due to placenta prævia and treated as such until there appears some positive evidence to prove it otherwise.

Prognosis.—It is one of the most difficult problems in obstetrics to prognose a case of placenta prævia. A case of lateral placenta prævia, which in the beginning appears easy and simple, ultimately becomes very severe and in some cases turns out to be fatal.

The prognosis depends on the following factors :—

(i) The condition in which a particular case first comes under treatment—if the patient has been received in an exsanguinated condition the prognosis is certainly not so favourable. Prognosis differs widely in 'booked' and emergency cases (Monro Kerr, 1933); 'booked' cases—3.1 per cent, and emergency—10.1 per cent death rate.

(ii) Environment—the outlook is certainly good if the patient is placed in the early stage in a well-organized maternity hospital equipped for abnormal cases.

(iii) The success depends more upon the skill of the attendant than upon any other single factor. To repeat the words of Rudolph Holmn (Davis, 1935)—'procrastination spells disaster in cases of placenta prævia'. At the same time it is equally true that injudicious and untimely interferences contribute a large share in causing high mortality, whereas the simplicity of operative procedures and its perfection materially alter prognosis.

(iv) Degree of prævia—it is always worse in central but fairly good in lateral.

(v) Postpartum hæmorrhage—this, even in small amount, which is of little significance in normal labour, is of material importance in a case of placenta prævia which has already been exsanguinated.

(vi) Infection—next to shock and hæmorrhage it is responsible for the high maternal mortality. In a five years' return (1926 to 1930) of the Glasgow Maternity Hospital—30 per cent deaths were due to sepsis. Referring to the table one finds that in the first two hospitals 6 out of 16 deaths were due to sepsis, *i.e.*, 37 per cent. This high maternal mortality in Bengal resulting from sepsis is due to the fact that nearly every patient was an emergency case and the tissue resistance and the vitality were very low on account of the prevalence of anæmia, malaria, kala-azar, etc. Hence the importance of maintaining rigid asepsis in making vaginal examinations in a suspected case of placenta prævia and also in any operative procedure. Infection is more common in cases following plugging adopted as a method of treatment.

Management.—As the condition is not preventable its treatment does not come under preventive midwifery although cases diagnosed in the antenatal clinics and kept under observation show better prognoses.

There are few more debated subjects in obstetrics than the treatment of placenta prævia. Before dealing with it, it is essential that the patient should be placed in the best environment. In this respect a well-equipped maternity hospital is the best, particularly in a case of central variety. In fact, the improvement in the mortality rate of this condition will depend largely on early hospitalization of the patient. Next preference goes to nursing homes. Unfortunately, these homes have not received much sympathy and popularity in this country, particularly in Bengal, excepting for special occasions. Europeans mostly patronize these homes; amongst the native population, few can do so because of lack of funds, social prejudices, etc. Conditions in these homes are much better in Bombay and Madras.

Lastly, comes the treatment in a private house. Of course, there is much to deprecate the domiciliary treatment of placenta prævia. In fact, in the British Isles, it is not generally adopted. But one has to modify the line of treatment according to the social customs and other prejudices prevalent in the country. In treating a case of placenta prævia in a private house, the practitioner with his assistants should be in constant attendance. He should not take any other emergency case in hand. All the armamentaria for use in a case of placenta prævia should be kept ready and the obstetrician should be within easy reach. Neglect to observe this rule sometimes causes disaster in a private house. But in any event, domiciliary

treatment is strongly contra-indicated in poor houses, in insanitary surroundings and also in cases of central placenta prævia.

The management can be dealt with according to the various methods at our disposal, but a better plan would be to consider the treatment according to the different clinical pictures the patients usually present.

For the convenience of treatment and according to the commonest conditions in which patients are found, the cases may generally be classified as follows :—

Group A.—When the patient is not in labour and the cervix is closed or just admits the tip of a finger in a multipara.

Group B.—When the patient is in labour or the cervix is dilated 2 fingers.

Group C.—Central—the placenta covers the whole of the internal os.

Group A

1. *In slight cases* (bleeding not exceeding 2 to 4 ounces)—*expectant treatment*—watchful expectancy with rest in bed and sedatives. Authorities differ in this line of treatment, once the diagnosis is established. In my opinion, a patient may be treated on these lines provided she is placed in a suitable environment, hospital or private house, where every possible arrangement has been made for emergency help. The signals of danger should be given to the nurse in writing and the armamentaria for the need of a case of placenta prævia should be kept ready. 'Expectant treatment is indicated in a case of an elderly primipara whose chance of becoming pregnant again is remote. It is contra-indicated in full-term pregnancy or when a patient is in labour and when the placenta covers the internal os, i.e., is central'.

2. *In moderate or severe cases*—plugging. This is the old Rotunda method prescribed for over a century (Eden and Holland, 1931).

Patients are often seen in the hospital that have been sent by private practitioners, as well as by other maternity homes under the City Corporation, after plugging which was performed in an improper and ineffective way. In order to be effective, this small but temporary life-saving operation in a case of placenta prævia must be done thoroughly and methodically. Plugging in a case of placenta prævia to be effective cannot be done without instruments of which only a few are necessary. It also requires good light, particularly in a private house, and an assistant to hold the legs. Plugging should be preceded by rupture of the membranes whenever possible and followed by application of a tight abdominal binder.

The patient should be catheterized every 8 to 12 hours. If no pain starts the plugs should be changed after 12 to 16 hours in the summer, 24 to 32 hours in the winter.

Group B

This is the commonest condition in which most of the placenta prævia cases are seen in India.

1. *If lateral (high placenta prævia)*.—Rupture the membranes and apply a tight abdominal binder. This is the ideal method of managing a case of placenta prævia with safety to the mother as well to the baby. In fact, this method contributes largely to lowering the mortality rate, but its application is limited only to this variety of case. Sometimes, rupture of the membranes has to be supplemented by forceps or craniotomy. Rupture of the membranes should never be done if the presentation is transverse.

2. *If marginal*.—Bleeding should be controlled by any one of the following methods and the remainder of the delivery left to nature, i.e., to be terminated slowly and spontaneously.

(a) *Pressure of half breech over the bleeding placental area*.—(i) In breech presentation—it is easy; a leg is to be brought down after rupturing the membranes. (ii) In head or transverse presentation (a) version, if possible external; otherwise bipolar followed by bringing down a leg. In the majority of cases, the head presents and external version is not possible and the cervix does not allow internal version—hence bipolar podalic version is the method of choice.

Bipolar podalic version (Braxton Hick's) is the old but efficient method of managing a case of placenta prævia. It can be performed anywhere and at any time and practically in all varieties of cases of placenta prævia, if the cervix admits only 2 fingers which in a case of multipara is not uncommon. The method requires only one assistant and practically no instruments, but some training on the part of the obstetrician is of immense value. After version a foot is brought down to the vulva, heel pointing upwards and traction is put on just sufficient to stop bleeding. No time should be lost to find out the upper or lower leg. Difficulties may be experienced, (i) in rupturing the membranes which are not always easy to reach in a case of placenta prævia, (ii) in turning the child if the legs are extended, (iii) in finding the leg (a mistake may be made with a hand), and (iv) the leg may slip from the hand near the internal os. These difficulties are to a certain extent caused by want of experience. During the efforts to overcome these difficulties, a patient in the hands of a young specialist may bleed profusely. In such an eventuality, it is advisable that the obstetrician should change his line of action. Plugging should be resorted to to stop bleeding and the patient treated for loss of blood; otherwise his firm determination is sure to cause disaster. This is the first part of the treatment which should be performed quickly but methodically. The remainder of the management should be left to nature and

all the rules of a breech presentation should be strictly followed. Traction is to be applied only when bleeding starts and the amount should be just sufficient to stop bleeding. The motto should be *quick version and slow extraction*. During the valuable interval in between, the patient should be treated for loss of blood. Negligence to observe this rule often causes disaster; I have seen patients, both in hospitals and in private houses, brought actually to a critical condition due to non-observance of this rule by young obstetricians, who in their attempt to secure 'double honours' institute early traction. It should always be remembered that *safety of the mother is always the first thing, and should not be sacrificed for the sake of the child*. It should never be forgotten that *anæmic patients stand shock very badly* and it is nowhere more true than in India because under normal condition the blood of the average Indian woman is much poorer than that of her European sister. This can be easily seen from the following figures:—

Healthy women between 16 to 35 years (1934)	Bengali (Dhar, 1934-1935)	Hæmoglobin (gram)	Erythrocytes (millions)	Colour index
	11.47		3.73	0.995
Healthy English women, the same age (Ben Jones).	13.9		5.01	1.00

Further, injudicious and energetic traction easily cause extensive laceration of the cervix in a case of placenta prævia, resulting in post-partum hæmorrhage.

In my personal experience both in hospital and private practice, the proper management of placenta prævia by this method terminates labour spontaneously in two to six hours after bipolar podalic version and in the majority of the cases with living children, unless the patient had already bled sufficiently to cause intra-uterine death, or a badly asphyxiated condition, of the child. Sometimes, the after-coming head requires some assistance.

(b) *If the head presents and the child is living:—Scalp traction is equally effective.*—This method was introduced by the late Dr. Willett (Bourne and Williams, 1932) in 1923. His preliminary report was based upon only a few cases in the City of London Lying-in Hospital. At first he used an ordinary strong volsellum and subsequently improved the instrument, which goes by his name (Willett forceps). Conditions to be fulfilled for its application are:—

- (i) the cervix must admit two fingers, loose,
- (ii) the patient should be in labour and
- (iii) the child must be living and there must be a head presentation.

The membranes are ruptured and the forceps applied, taking a good grip of the scalp.

My personal experience of this method is very limited. It is not always easy to apply the

forceps on the head, which is usually floating in placenta prævia, and to take a good bite of the scalp. Besides, unless it is applied near about the occipital region, there will be extension of the head, which causes difficulty in engagement under normal condition, far more so in a case where the lower uterine segment is occupied by the placenta. Sometimes, the scalp is cut through; this gives rise to sepsis which a newborn baby stands badly. Traction sufficient to stop bleeding only is required, i.e., average 1 to 2 lbs. to the handle of the forceps connected with a pulley at the foot end of the bed.

(c) *The pressure of a hydrostatic bag.*—15 years ago this was the standard and favourite method of treating a case of placenta prævia. The bag has now become an obsolete instrument in hospitals in Calcutta, and it has fallen into disrepute in the hands of British obstetricians; there are many reasons for condemning its use. But in America the application of the hydrostatic bag still enjoys a high reputation in nearly every clinic.

(d) *Plugging:—Cervico-vaginal.*—Once a favourite method of treatment in this variety of placenta prævia, it is not very popular now. The gradual decline in popularity is probably due to—

- (i) Unreliability of controlling hæmorrhage. Following this method the bleeding which sometimes continues may become either external or internal.
- (ii) Sepsis following plugging is high, giving rise to an increase in morbidity.
- (iii) Displaces the presenting parts.
- (iv) Often requires other methods to supplement it.
- (v) Possibility of rupture of the uterus if plugs are not timely removed—at least plugging was the only interference in H. D. De Sa's case of spontaneous rupture of the uterus in placenta prævia mentioned below.

Still, cervico-vaginal plug has a place as a method of treatment in cases of placenta prævia,

- (1) as ambulatory treatment,
- (2) when bipolar version fails, and
- (3) in central placenta prævia when the patient's condition is too low for Cæsarean section.

(e) *Cæsarean section.*—The increasing popularity of the Cæsarean section has led to its widespread application in the hands of young obstetricians and it has replaced the art of midwifery in several conditions. This encouragement is simply due to its low mortality. Perhaps this is a transitional phase and a sufficiently long experience will turn the balance in the opposite direction. To a serious and thoughtful obstetrician the application of Cæsarean

section in marginal placenta prævia is limited to, (i) rigidity of the cervix and other obstruction to vaginal manipulation, (ii) elderly primipara—if the patient be very anxious for a child, and even in such a case the condition of the child and the possibility of prematurity should be duly considered.

Group C

It has already been mentioned that hospital is the best and safest place for such cases. Cæsarean section is to be performed if the patient's condition is good. If the patient has already lost a considerable quantity of blood, plugging should be resorted to followed by treatment for the loss of blood by saline or blood transfusion. When the patient's condition improves, labour should be terminated by classical Cæsarean section, irrespective of the child's condition. If the patient is in unfavourable surroundings, where Cæsarean section is not possible or safe or the medical attendant is not skilled to abdominal surgery, rupture of the membranes by going through the placenta and bringing down a leg should be adopted. Considerable hæmorrhage may take place, but there is no other alternative in such circumstances. In fact, this is the only method of treating a case of central placenta prævia in rural areas where there is no facility for opening the abdomen.

Further, if the patient is brought in a collapsed condition, which is not a rare event in obstetric practice in our country, the patient should be carefully removed from the ambulance and treated for shock and loss of blood. These patients have little blood to lose, hence no interference should be attempted till they come round. Usually these cases are fatal within a few hours.

Next comes the *management of the third stage*. The importance of smooth performance of this stage of labour in a case of placenta prævia cannot be over-estimated. A large percentage of cases of placenta prævia suffer from postpartum hæmorrhage and some of them in such profuse amounts that the patients die before anything can be done for them. Postpartum hæmorrhage even of moderate degree, which is of no significance in an otherwise normal case, becomes a lethal factor in a case of placenta prævia which has already been exsanguinated. If the placenta is not cast, it should be squeezed out or manually removed without delay. If the placenta is cast, intra-uterine plugging should be done followed by treatment for loss of blood. Tentative methods to arrest bleeding should not be adopted.

Saline transfusion

The urgent necessity for saline transfusion in a case of placenta prævia cannot be over-estimated. In fact, it is the team work of immediate saline transfusion and skilful, prompt and judicious surgical or obstetrical

interference, combined with safe anæsthesia, which brings success in a desperate case of placenta prævia in a well-equipped maternity hospital. In private houses, the saline-transfusion apparatus should be kept ready as a routine practice in any case of placenta prævia. A case, which in the beginning appears mild and simple, often turns out to be severe and complicated as the labour advances and interference commences.

Blood transfusion

The most efficient and scientific way of treating a case of acute hæmorrhage is by supplying the system with the same vital fluid. If carefully performed, it is practically devoid of risk. In fact in nearly every clinic in the British Isles a case of placenta prævia is 'grouped' immediately on admission and the suitably-matched registered donor is informed and kept within easy reach. In Bengal, transfusion has not acquired such popularity yet, possibly due to want of suitable organization and partly due to social prejudice and ignorance of the people.

The responsibility of the accoucheur does not end with the termination of labour. A patient in a private house should be watched for bleeding for at least four hours before she is handed over to a nurse and things for plugging should be kept ready during this period.

Morbidity

A considerable number of cases run a morbid temperature and some of them are definitely septic. In a five-year return of the hospitals in Calcutta we find the following figures:—

	Per cent
Eden Hospital	18
Carmichael Medical College Hospitals	45
Chittaranjan Seva Sadan ..	49
Average morbidity, Calcutta ..	37
Madras	15
Bombay	19.7
Average morbidity in India ..	24

Hence precautionary measures should be taken to cope with it. In a suspected case, serum in adequate doses should be administered early. The patient's strength should be maintained by easily assimilable diet with plenty of glucose, stimulants and vitamins.

Mortality.—According to the table under review, the average mortality rate of placenta prævia treated in Indian conditions is 9 per cent.

	Per cent
Eden Hospital	9.7
Carmichael Medical College Hospitals	14.25
Chittaranjan Seva Sadan ..	9
Average mean figures:—	
Calcutta	Per cent
Madras	11
Bombay	13
	4

Credit is due to the staff of the Nowrosjee Wadia Maternity Hospital, Bombay, one of the biggest institutions in India, where the average mortality is only 4 per cent. In the years 1932 and 1934, the number of cases of placenta prævia treated in this hospital were 24 and 43, respectively, without any mortality. These are not only the lowest figures in India but certainly far below those in many hospitals in the British Isles.

	Per cent
Queen Charlotte's ..	9
St. Mary's (Manchester 1933) ..	6
Royal Maternity (Glasgow 1932) ..	11

This low mortality in the Bombay Hospital may be due either to many cases being diagnosed in the antenatal clinics or perhaps the women in Bombay are more frightened of bleeding than their sisters in other provinces and go to hospital early; naturally, the hospital receives them in a better condition. But one interesting fact which cannot be overlooked is that the methods of treatment in this hospital were rupture of the membranes and version, with occasional application of Willet's forceps. Perhaps these methods of treatment formed an important factor in producing such brilliant results.

Summary

Placenta prævia which constitutes one of the important and common causes of antepartum hæmorrhage has been considered from its various clinical aspects.

The statistics of the important hospitals of Calcutta, Madras and Bombay have been considered with special reference to the incidence, parity, morbidity and mortality. The management of the condition has been fully dealt with from the point of view of the commonest conditions in which patients are generally seen in Bengal. Practical difficulties as encountered in India in the course of treatment have been explained and the methods of coping with them have been described.

Interesting cases have been fully described.

Case 1.—Age 18, admitted to the Carmichael Medical College Hospitals on the 17th September, 1935, at 0-15 p.m., with a history of seven months' amenorrhœa complaining of sudden distension of the abdomen for four days, and slight pain in the lower abdomen for 24 hours.

She was a primigravida. The height of the uterus was to the level of the xiphoid cartilage; it was globular in outline, prominent in front, very tense but not tender, thrill present. The skin over it was tense and shining. The foetal parts were not felt, nor was the foetal heart sound heard. Pulse/resp. rate=114/22, volume and tension good.

Per vaginam.—Os two fingers dilated, cervix thick, head presenting, membranes present but not tense. The patient bled slightly during examination and on further exploration placental tissue was felt in the left post-lateral quadrant of the cervix. The membranes were ruptured with a Kocker's forceps but only 2 to 3 ounces liquor amnii came out. The head was low down in the cavity. The height and tension of the uterus remained the same. An attempt at scalp traction, cut

through the scalp. As there was no active bleeding, the patient was kept on the table under watchful expectancy and given sedatives. A diagnosis of twins with hydramnios of the second sac, complicated by lateral placenta prævia, was made.

At 8-10 p.m., when the cervix was taken up and the os was 3 fingers, loose, a dead and partly mummified child was born spontaneously. The membranes of the second sac were ruptured artificially and six pints of clear fluid came out, followed immediately by the delivery of a dead but not mummified child with talipes of both feet. The placenta followed the birth of the child. It was uniovular with only two amniotic sacs. There was no post-partum hæmorrhage. The patient had an uneventful puerperium.

It was an interesting case of twin pregnancy with acute hydramnios of the second sac and talipes of the second foetus complicated by lateral placenta prævia.

Case 2.—Age 28, admitted to Chittaranjan Seva Sadan at 8-40 a.m., on 27th July, 1935; she came in from Bugnan, about 20 miles from Calcutta, with history of (i) amenorrhœa for nine months, and (ii) painless profuse bleeding for the last five days, off and on, with sudden onset and no labour pains.

Temperature 100.4°F. Pulse/resp. rate=124/30. Pulse soft and irregular; respiration, somewhat difficult. She was very anæmic, extremities cold, and not responding to questions properly. Heart sounds weak and quick; lungs—clear.

The uterus was the size of eight months' pregnancy, soft, not tender; no painful contraction present. No foetal heart sounds. Head presenting and floating.

Per vaginam.—Vagina full of blood clot, cervix taken up considerably, admitted 2 fingers.

Placental tissue felt in the left post-quadrant. The patient started bleeding freely. The membranes were ruptured, about 10 ounces of liquor amnii drained out and the cervix and vagina tightly plugged with gauze and cotton-wool. The bleeding stopped. A sterile pad and a tight abdominal binder put on. The pulse of the patient became very soft, feeble, rapid and irregular.

Subcutaneous saline Oii given statim; oxygen inhalation; foot end of the table raised. The patient kept warm under blanket and hot water bottles to the sides.

At 10-30 a.m.—Normal saline Oii.	} Intravenously.
Glucose 25 per cent 40 c.c.	
Cardiozol 1 c.c.	

8 p.m.—The pulse condition slightly improved but still soft and rapid not justifying any interference.

Pulse/resp. rate=120/40. Temperature 100.6°F.

There were no labour pains and no blood discharge *per vaginam*. The patient complained of pain all over the body—some evidence of reaction.

Rectal saline 6 oz. every four hours continued.

3 a.m.—Pulse imperceptible in both wrists. Heart sounds foetal in character 146; respiration 46, laboured. No blood discharge *per vaginam*—uterus contracting, now and again; adrenalin 1 c.cm. injected.

6 a.m.—The condition gradually grew worse and the patient expired.

After death, on removal of the vaginal plug a good amount of fluid blood came out through the cervix and the placenta was found separated considerably. These revealed that hæmorrhage continued and remained concealed after plugging; this was probably the cause of death.

Case 3.—Age 24, fourth pregnancy, admitted to Chittaranjan Seva Sadan at 5-45 p.m. on 7th November, 1934, with history of (i) amenorrhœa for ten months and (ii) sudden onset of bleeding since 4 p.m. not attended with any pain, temperature 99.6°F., pulse/resp. rate=100/22.

Uterus size of ten months' pregnancy, soft, no pain, foetal parts easily palpable. Head presenting, high up and floating.

Foetal heart sounds in the right lower quadrant.

Per vaginam.—Bleeding present; cervix nearly taken up; os 2 fingers, loose through the cervix the placental tissue only felt all round; head presenting high up.

The patient started bleeding profusely immediately after examination.

6-15 p.m.—Vagina was tightly plugged with iodoform gauze and cotton-wool—without rupturing the membranes.

The patient was prepared for Cæsarean section. She was restless but had no pain; pulse 120 soft and volume small.

Temperature 98°F. Blood pressure 90/75.

Normal saline 0.5%

Glucose 25 per cent 50 c.c. } Intravenously.

Continuous oxygen given.

9 p.m.—The patient's condition improved slightly; restlessness disappeared. Pulse soft and moderate tension; classical Cæsarean section was performed—baby living, male, 6 lb., though asphyxiated it revived—no post-partum hæmorrhage. The usual post-operative treatment was done.

The patient recovered from the shock without any trouble and the baby started breathing easily.

8th November, 1934, 4 p.m.—Suddenly the baby started to bring out profusely bright blood with froth through the nose and mouth, it grew pale, gasped, and died soon after, before any treatment could be given.

Post-mortem examination of the baby did not reveal any abnormality excepting a few hæmorrhagic spots on the anterior wall of the heart along the course of the coronary vessels and dark areas of consolidation here and there in both lungs.

The puerperium up to the 19th day was uneventful, only the temperature went up to 99.6°F. on two occasions.

On the 20th day the patient started bleeding; this persisted for three to four days. On the 24th day of observation the uterus was found bulky, mobile, cervix patulous admitting a finger easily and through which a soft polypoid mass attached by a pedicle was found hanging. It was removed and the uterus was swabbed out with iodine and the bleeding stopped—placental polypus. The patient went home—cured on the 28th day (6th December, 1934).

This was a case of central prævia with severe bleeding, treated by vaginal plugging, followed by Cæsarean section.

In conclusion, I acknowledge with thanks the information supplied by the Superintendent of the Eden Hospital. I also express my indebtedness to the Principal, Carmichael Medical College, and the senior visiting surgeon, Chittaranjan Seva Sadan, for permitting me to publish the returns and cases. My thanks are also due to the intern officers of the above hospitals for helping me in collecting the figures.

PUERPERAL SEPSIS : A REVIEW

By P. C. DUTTA, M.B., F.R.C.S.(E.), D.G.O.
CAPTAIN, I.M.S.

Civil Surgeon, Jullundur

A good deal of work has lately been done by various clinicians and laboratory workers on this subject. Some of the results are very useful while others are of doubtful utility. A summary of our present state of knowledge may help that most useful medical member of society, the general practitioner.

It has been very rightly said by Solomons (1931) that the best treatment of puerperal sepsis is prevention. The first essential to attain this is to maintain the physical condition of the mother, so that she may be able to resist infections. This can best be achieved by proper antenatal care, adequate nutrition and the prevention of anæmia. Secondly, the attendant must be thoroughly conversant with the mechanism of labour. This will restrict meddlesome midwifery to the minimum, no interference will be made before it is really indicated, there will be no unnecessary use of forceps, operations, and so on. The attendant must be able to gauge the powers of the uterus, when and how far it has to be helped and when it has to be soothed. This can only be acquired by thorough training and careful observation of cases throughout labour. Thirdly, the knowledge of the source of infection and methods of prevention. It must be realized that it is the neglect of simple things that cause 80 per cent of puerperal infection.

Without going into unnecessary details and discussions it can safely be stated that in nearly all cases of sepsis the infection is caused by introduction of organisms from outside. They may be introduced by the attendant or by the patient herself. Dora Colebrook (1935) and Griffith (1934) found that the 11 types of hæmolytic streptococci which cause the majority of puerperal cases are also found in infections of the throat and Colebrook and Maxted (1933), after a series of very thorough and painstaking investigations, conclude that in most cases the source of the infection is the throat. It may be the patient's throat, the attendant's throat or the throat of some other person with whom the mother came in contact. The organisms may be lurking about in a handkerchief, a mattress, a not-properly-sterilized wash-hand bowl and similar articles with which the mother comes in contact directly or indirectly during labour. As a matter of fact any infection in the house, e.g., otitis media, erysipelas, nasal sinus infection, whitlow or even a trivial infection of a finger, impetigo, etc., are very real sources of danger. The possibility of puerperal sepsis arising by streptococci from the throat, through the blood stream, has practically been ruled out. The microbe is transferred by some external route.

Credit is due to the staff of the Nowrosjee Wadia Maternity Hospital, Bombay, one of the biggest institutions in India, where the average mortality is only 4 per cent. In the years 1932 and 1934, the number of cases of placenta prævia treated in this hospital were 24 and 43, respectively, without any mortality. These are not only the lowest figures in India but certainly far below those in many hospitals in the British Isles.

	Per cent
Queen Charlotte's ..	9
St. Mary's (Manchester 1933) ..	6
Royal Maternity (Glasgow 1932) ..	11

This low mortality in the Bombay Hospital may be due either to many cases being diagnosed in the antenatal clinics or perhaps the women in Bombay are more frightened of bleeding than their sisters in other provinces and go to hospital early; naturally, the hospital receives them in a better condition. But one interesting fact which cannot be overlooked is that the methods of treatment in this hospital were rupture of the membranes and version, with occasional application of Willet's forceps. Perhaps these methods of treatment formed an important factor in producing such brilliant results.

PUERPERAL SEPSIS : A REVIEW

By P. C. DUTTA, M.B., F.R.C.S.(E.), D.G.O.
CAPTAIN, I.M.S.

Civil Surgeon, Jullundur

A good deal of work has lately been done by various clinicians and laboratory workers on this subject. Some of the results are very useful while others are of doubtful utility. A summary of our present state of knowledge may help that most useful medical member of society, the general practitioner.

It has been very rightly said by Solomons (1931) that the best treatment of puerperal sepsis is prevention. The first essential to attain this is to maintain the physical condition of the mother, so that she may be able to resist infections. This can best be achieved by proper antenatal care, adequate nutrition and the prevention of anæmia. Secondly, the attendant must be thoroughly conversant with the mechanism of labour. This will restrict meddlesome midwifery to the minimum, no interference will be made before it is really indicated, there will be no unnecessary use of forceps, operations, and so on. The attendant must be able to gauge the powers of the uterus, when and how far it has to be helped and when it has to be soothed. This can only be acquired by thorough training and careful observation of cases throughout labour. Thirdly, the knowledge of the source of infection and methods of prevention. It must be realized that it is the neglect of simple things that cause 80 per cent of puerperal infection.

Without going into unnecessary details and discussions it can safely be stated that in nearly all cases of sepsis the infection is caused by introduction of organisms from outside. They may be introduced by the attendant or by the patient herself. Dora Colebrook (1935) and Griffith (1934) found that the 11 types of hæmolytic streptococci which cause the majority of puerperal cases are also found in infections of the throat and Colebrook and Maxted (1933), after a series of very thorough and painstaking investigations, conclude that in most cases the source of the infection is the throat. It may be the patient's throat, the attendant's throat or the throat of some other person with whom the mother came in contact. The organisms may be lurking about in a handkerchief, a mattress, a not-properly-sterilized wash-hand bowl and similar articles with which the mother comes in contact directly or indirectly during labour. As a matter of fact any infection in the house, e.g., otitis media, erysipelas, nasal sinus infection, whitlow or even a trivial infection of a finger, impetigo, etc., are very real sources of danger. The possibility of puerperal sepsis arising by streptococci from the throat, through the blood stream, has practically been ruled out. The microbe is transferred by some external route.

The practice of ablution with bare hands, after defæcation is, in my opinion, a constant source of danger in obstetric practice, unless the hands are thoroughly washed and disinfected. Certain investigations convinced me that fæcal organisms could be grown from the hands, after ordinary washings as is done in a day's work, after 24 hours.

Lately, our attention has been drawn to post abortal and puerperal infection by the gas gangrene bacillus and I have seen occasional cases of this. I do not think it is very uncommon in our country. These infections are nearly always caused by fæcal contamination. In Europe and other countries this may reasonably be due to extension of infection from the mother's anus, whereas in this country where the woman washes herself more or less thoroughly after defæcation, they may be introduced from the patient's or from the attendant's hands. Bearing these facts in mind, I would advise that the doctor should take every precaution to avoid contamination of his hands with fæcal matter. I leave the method to individual choice and discretion.

I. Prevention of introduction of organisms

Before the actual confinement is undertaken a thorough investigation must be made if there is infection, specially streptococcal, in the family or outside the family with whom the mother comes in contact, and strict measures must be adopted to avoid these. If any sort of streptococcal infection is present in the house, the mother should be confined in a hospital or nursing home, because the organisms may gain entrance by so many insidious ways that it is practically impossible to prevent in a private house.

In 20 per cent of septic cases, it was found that infection with the same type of organism was present in some member of the family and in another 20 per cent the mother came in contact with someone suffering from streptococcal infection of the same type. Bedding and linen may be infected from the air by droplet infection from some member of the family and it must be realized that the organisms may persist in these articles for some time. Similarly, basins, towels, handkerchiefs of the mother or of the attendants are constant sources of danger.

Hands of the attendant

Thorough washing with soap and water is the most important item in the antiseptic technique. They must be thoroughly washed with soap and water and scrubbed with a nail brush. Ordinary yellow household soap is better than refined toilet soaps and soft soaps. Antiseptic soaps, e.g., those incorporating carbolic acid or coal tar products are slightly more bactericidal than ordinary yellow soap.

After washing the hands for two to three minutes and soaking them for three minutes in

perchloride of mercury (1 in 1,000) or lysol (1 in 60), as is usually done, organisms can always be cultivated from the hands and fingers. Colebrook (1936) has shown that washing with ordinary soap and water and then rubbing the hands with dettol cream cleanses the hands more thoroughly of the organisms than any other practicable method known at present.

Cruikshank found that the hands may be reinfected from the air as early as two minutes after washing and disinfection by the ordinary antiseptics. Colebrook demonstrated that this reinfection can be prevented for two to five hours if 10 per cent dettol or 30 per cent dettol cream is rubbed on the hands. He strongly advises this procedure with bare or gloved hands and this should be repeated every two hours.

Dettol has an oily base which sticks on to the surface forming an invisible film, and organisms coming in contact with it are destroyed. The effect lasts from two to five hours.

Masks

These should be used in all cases if possible. In the hot weather it is better to use a two-piece mask. A strip of old towelling (old towel soaks better) about 2 inches wide and 8 inches or 10 inches long with tapes at either end is tied over the forehead and is very necessary to prevent perspiration dripping from the forehead on to the hands, instruments or perineum. The mask proper is made of a piece of linen 8 to 10 inches by 6 to 8 inches. The central part of this is cut off leaving a margin of about 2 inches on all sides. A six-fold piece of gauze is sewn in to fill up the gap. This will keep the face fairly comfortable even in the hot weather.

Gloves

They must be thoroughly sterilized. The outer side of the glove must not be contaminated when putting them on and every doctor and medical student should learn how to put on a pair of gloves without 'mauling' them. When the gloves are put on, the fingers should be adjusted with a sterile piece of gauze. Smearing them with 10 per cent dettol or 30 per cent dettol cream will prevent reinfection from the air.

Basins and utensils

They must be thoroughly disinfected either by boiling, burning spirit in them, or scouring them with some strong antiseptic, e.g., a few drops of 10 per cent lysol, pure dettol, etc.

Water for confinement

If cold sterile water is not available, cyllin one drachm in three pints of water, will sterilize it for the purpose.

Patient's hands

In about 4 per cent of normal women, Colebrook (1936) was able to grow the same type of

organisms from the mother's hands as are usually responsible for puerperal infection. It is almost unbelievable how often the woman in labour pain will put her hands in this so-closely-guarded spot. Therefore, the patient's hands should also be thoroughly scrubbed and washed and rubbed with dettol.

Preparation of vulva and perineum

Vulva and perineum are cleaned with soap and water and painted with an antiseptic, e.g., methylene blue or crystal violet. Colebrook recommends 30 per cent dettol cream and has reported very good results by using this.

Vaginal examination

Unnecessary examinations must be avoided. In a normal case no interference should be made with the vagina and it should not be painted with any antiseptic.

When vaginal examination has to be made, the vulva should be thoroughly rubbed with some antiseptic such as crystal violet, methylene blue or 30 per cent dettol cream. In making a vaginal examination the vulva should be widely separated with the left hand so that no organisms are pushed into the vagina from outside. The vaginal examination must be done at least five minutes after painting the part with the antiseptic. When an examination is made, it must be done thoroughly and the attendant should not bring out the fingers until he is satisfied. Repeated withdrawal and introduction of the fingers will only help infection. The disinfectant should be re-applied every three hours and before any internal manipulation.

Douching the uterus after operative delivery

An extract from the final report of the departmental committee on maternal mortality and morbidity is here quoted: 'It is practically certain that antiseptics will fail to kill pathogenic bacteria at the termination of labour when the whole genital tract is bathed in blood and serum. Firstly, because the microbes at the time if not already in the tissues are to a large extent caught up in the meshes of the blood clot, and no antiseptic can diffuse into the blood clot in a concentration sufficient to kill microbes unless it is present for a long period in a very high concentration—a condition which cannot be maintained in the genital tract because of the constant outward stream from the placental site. Secondly, antiseptics will fail in these circumstances because all of them when brought into contact with undiluted blood and naked fixed tissue cells such as those of the placental site will combine in great mass and in so doing will forfeit their power to combine with and kill the relatively negligible mass of microbes. Not only will the antiseptics fail in these circumstances but they will probably often do harm. For it has been clearly shown that in contact with the blood most of the antiseptics

destroy the leucocytes upon which the bactericidal efficiency of the blood chiefly depends. There can be little doubt that the mother's best chance of escaping infection lies in the imprisonment of the microbes in the blood clot and their destruction here by the agency of the leucocytes'.

II. Prophylactic treatment of sepsis

Maintaining the mother's health in perfect condition in the antenatal period, as has already been stated, is of supreme importance. This has to be done with adequate dietary. When the diet is deficient, proprietary preparations should be used to prevent anaemia and vitamin deficiency. In India where the average doctor has to work under conditions far from ideal, he must improve this, his first line of defence. For this purpose some concentrated preparation of vitamin A is most useful.

Green-Armytage and Dutta (1932) years ago recommended small doses of quinine in the last few months of pregnancy. This is now advocated by many other authorities. It is doubly useful in this country. It not only increases the resistance of the patient but will keep the old malarial infection, from which most people suffer, at bay, during the puerperium. It is a common experience in this country that old malaria often flares up at the puerperium. Moreover small doses of quinine will improve the tone of the uterine muscle and ensure efficient contraction during labour. This in its turn will lead to less interference, less incidence of forceps delivery and consequently less chance of sepsis. Primary uterine inertia due to flabbiness of the uterus is so common in this country that it is a real help. Even after a normal delivery it is very wise to put the woman on a mixture containing ergot and quinine for a few days to ensure a well-contracted uterus and to stop the old malaria.

Thompson (1935) recommends $\frac{1}{2}$ gr. doses of calcium sulphide thrice daily as a routine from the day of admission or preferably from the prenatal period. It is given in a capsule with halibut oil. The treatment is cheap and efficient.

Antistreptococcal serum

Cameron and Thompson (1931) obtained very good results with this, but lately they have reported far better results with halibut oil and calcium sulphide.

Solomons (1935) during the tenure of his mastership of Rotunda Hospital used 20 c.cm. of antistreptococcal serum as a routine prophylactic in all difficult cases and reported greatly improved results. He uses it after all operative deliveries except low forceps.

Colebrook (1934) is of opinion that the prophylactic action of serum is doubtful, and, on the analogy of experimental animals, states that the serum may interfere with the ability of the patient to deal with infections in a

previously sensitized patient, and as such may be positively harmful.

Iodine.—In a previous paper I (Dutta, 1929) remarked that iodine given as a prophylactic was found useful. I have used ordinary aqueous solution of iodine with potassium iodide intravenously for the purpose and confirm my previous observations. Moreover, this drug being very cheap and always available in every dispensary is within everybody's reach. For curative purposes, I do not think it to be of much use.

Prontosil.—This has been used for prophylactic purposes with good results.

As noted above quinine and ergot should be given in all cases for the first eight days. It does not matter what preparations are used so long as they are effective.

Many other antiseptics have been recommended from time to time but they have not stood the test of time.

III. Treatment of puerperal sepsis

The modern treatment of puerperal sepsis is to increase the resistance of the patient.

Mild cases get well with postural drainage, hot fomentations to the abdomen, ergot, quinine and possibly 20 c.cm. of antistreptococcal serum combined with fresh air and good sleep. Digital exploration should never be done unless a piece of placenta has been left behind.

Remington Hobb's treatment.—This consists of intra-uterine injection of sterile glycerine. It has been recommended that the injection should be done three times a day through a special catheter kept in the uterus. This may be possible in a special hospital where trained assistants are available. In the average district hospital or private practice it is not possible and I recommend injection of 20 c.cm. glycerine once a day. This method of treatment is specially useful if the lochia has stopped. A speculum is passed, the cervix is cleaned and 20 c.cm. of glycerine is injected through an ordinary female catheter passed into the uterus.

Intramuscular injection of 5 grains of quinine every other day has also been recommended.

If the blood shows a poor leucocytic response injections of sodium nucleate may be good.

Prontosil

It is a chemotherapeutic agent for streptococcal infection and very encouraging results have been reported by certain German observers. This has recently been confirmed by Colebrook (1936). I used it in 15 bad and moderately severe cases: there were no deaths.

One ampoule is injected intramuscularly two to three times a day. At the same time one to two tablets or more are given three times a day. The tablets are chewed after meals with plenty of water. The amount given by injection may have to be increased to 60 to 90 c.cm and may

have to be repeated depending on the seriousness of the illness and condition of the patient. Generally not more than 20 c.cm. are required each day combined with oral administration as indicated above.

When the fever subsides and general condition improves, treatment may be continued with tablets alone.

The occasional occurrence of reddish urine following the administration of prontosil is due to the excreted dye-stuff and has no pathological significance.

Blood transfusion

Of all the life-saving methods of treatment that have been introduced in medicine in the last few years, blood transfusion stands out pre-eminent. Even in obstetric practice it has proved so valuable that we thought it advisable to include a detailed description of the technique in the latest edition of the textbook of midwifery with which my name is associated. It is exceptionally useful in severe puerperal septicæmia, specially those cases associated with anæmia. Even a small quantity of blood (100 c.c.) will produce a splendid effect. Not more than one pint need be given at a time, but it has to be repeated as often as is necessary.

Blood transfusion is not a difficult operation and, in my opinion (Dutta, 1936), can be carried out even in a rural dispensary and without any special instrument, particularly if small quantities are required. In a town where assistants are always available it can easily be carried out in private practice. Only one thing one has to be certain of and that is, being able to test the compatibility of the bloods. This is easy for one who has seen blood grouping done by a competent person.

Operative treatment

It is beyond the scope of this paper to enter into detailed description of different surgical procedures and their indications. It should however be remembered that draining the pouch of Douglas by posterior colpotomy is very useful when there is a collection of fluid in the pouch; also that a pelvic abscess should be opened just above the inguinal ligament.

In a serious case, an operation like hysterectomy or ligation of the ovarian vein will kill the patient, whereas mild cases will recover without any operation. Hysterectomy is only indicated in cases of abscess in the wall of the uterus, sloughing fibroid and ruptured septic uterus.

IV. Post-abortion and puerperal gas gangrene

Special mention of the above infection is necessary. The infection, as I have already stated, is not very uncommon and with better knowledge and more thorough bacteriological diagnoses it may be possible to find out the frequency of the infection in this country. Recently Hill (1936) reported 30 cases occurring in one hospital within two years, so it

appears that it is far more common than we think it to be.

Source of infection.—This is generally from the rectum. Faecal contamination is very liable to occur after an enema. In post-abortion cases, criminal abortion is a fruitful cause.

The organisms can be grown from the hands of medical attendants after washing and drying, less often after thorough scrubbing, and in some instances after thorough scrubbing and putting on wet sterilized gloves (Hill). That is why I have particularly mentioned the avoidance of faecal contamination of the hands, thorough scrubbing and putting on of the gloves in the right way.

Symptomatology.—This may be considered under the following headings:—

- (i) General and local signs of sepsis.
- (ii) Jaundice, most marked in the face and body, least in the legs. It comes on early, develops rapidly and quickly and is soon followed by—
- (iii) Cyanosis, specially of the fingers and toes. Absence of cyanosis is a good omen.
- (iv) Pulse rises quickly to about 140, is of low tension, soft and running. Signs of peripheral circulatory failure are present.
- (v) Temperature varies between 100 and 102.
- (vi) Urine is very small in quantity, and a sample may have to be obtained by catheter for examination. It is of port-wine colour, containing hæmoglobin, methæmoglobin and red-blood cells debris. Albumen is always present. The disease practically always ends in renal failure.
- (vii) Blood serum is of Burgundy colour due to hæmolysis.
- (viii) Within a few days the skin becomes very dark and the conjunctiva may assume a chocolate colour.
- (ix) The placenta is dirty pinkish-grey colour, soft, friable and spongy. The syndrome develops with amazing speed. It may be retarded or modified, but is only exceptionally arrested by therapy.

Diagnosis.—It is very difficult to diagnose puerperal cases early. The symptomatology is not evident till the very end, and, as it is often associated with a dead child or toxæmia, it is further obscured.

Jaundice, increasing pulse rate out of proportion to an evident pathological lesion, sudden collapse, increasing pain of the uterine muscle may indicate the lesion.

In severe and late cases gas crepitus of the lower abdomen may be evident.

Treatment.—Prophylactic—20,000 to 40,000 international units of gas gangrene serum.

Curative—total hysterectomy in early cases.

Forty thousand units of serum should be given intramuscularly as soon as it is diagnosed and repeated every 12 hours for at least three days. In grave cases a dose of 40,000 to 60,000

(Continued at foot of next column)

AN APPARATUS FOR THE DISTRIBUTION OF ANTIGEN EMULSION IN THE KAHN TEST

By N. SESHADRINATHAN

and

B. TIMOTHY

(King Institute of Preventive Medicine, Guindy)

For testing every sample of blood the Kahn antigen emulsion has to be distributed in three varying volumes with the Kahn pipette. When a number of tests have to be performed, the time, labour and eye-strain involved in carefully transferring the antigen emulsion to the bottom of each tube are factors which require to be considered.

The Kahn antigen emulsion does not remain homogeneous; when kept for more than a minute or two, the particles settle down unless the emulsion is constantly stirred up.

Donald's drop method used in the Wassermann test was found unsuitable for the Kahn test. The particles in the emulsion separated out and clogged the fine end of the delivery tube. An ordinary Wright's pipette with the tapering end calibrated to deliver 0.125 c.cm. per drop and with which small volumes of antigen could be taken at a time was found

(Continued from previous column)

units has to be given intravenously and repeated daily for two or three days.

To prevent renal failure glucose and calcium gluconate should be given intravenously with normal saline.

Blood transfusion is indispensable for saving the patient with hæmolysis.

Plenty of fluids with alkalies should be given by the mouth.

unsatisfactory. The emulsion, being heavy, flowed down too rapidly and the rate of dropping was not easily controlled. To overcome this, a bend was made just above the delivery end to give the pipette the shape of a bayonet. This bend produced a throttling effect on the flow of the antigen emulsion. With such a pipette, which was good enough for a small number of bloods, and ensured speedy distribution of the antigen emulsion, the rate of flow of the drops was not always uniform, especially towards the end of a series of tests when the finger muscles were naturally fatigued. It was, therefore, thought that a mechanical device for dropping the emulsion would be good.

An apparatus, the details of which are given below, was devised for this purpose. By means of this the antigen emulsion could be sucked up into a pipette in small quantities at a time and delivered in regulated drops by means of hydrostatic pressure. (For this suggestion we are thankful to Mr. Sukumaran, Lecturer in Electrical Engineering, Engineering College, Guindy.)

The apparatus consists of :

(1) A Woulfe's bottle with three necks and ground-in stoppers. The side necks have one delivery outlet and one syphon tube attached respectively (marked A in the diagram).

An apparatus for the distribution of antigen emulsion in the Kahn test.

(2) A separating funnel fitted with two stopcocks one below the other and passing through the central neck of the Woulfe's bottle. The mouth of the separating funnel is fitted with a rubber stopper through which a Marriot's tube is passed (marked B in the diagram).

The apparatus is fitted as in figure. Care should be taken to see that all connections and stoppers are quite airtight. The Woulfe's bottle

and the separating funnel are filled with tap water. The delivery pipette, which is drawn out to deliver 0.125 c.cm. of antigen emulsion per drop (the outer diameter of the end to fit into no. 54 Starret's drill and wire gauge), is attached to the delivery tube of the Woulfe's bottle by a short length of rubber tubing. The pipette is held vertically in position by a wooden clamp as shown in the figure, just high enough to allow the racks of tubes to pass under to receive the drops of emulsion. The syphon arrangement is fitted as in the figure. To set the syphon into action, close the delivery end of the bottle, open both stopcocks (S_1 and S_2) and press the pinch cock at the end of the syphon tube. This drives the water in the bottle to fill up the syphon tube and set it working. On releasing the pinch cock, the syphon remains closed.

The antigen emulsion having been prepared in the usual way, is sucked up into the pipette (about 1 c.cm. at a time) as follows :—

The vial containing the antigen emulsion is brought under the pipette so that the tip of the latter dips into the emulsion. The syphon is released by pressing the pinch cock and the antigen emulsion will rise up in the pipette. When sufficient amount has been sucked up, the pinch cock is released. The fluid remains held up in the pipette.

The lower stop cock of the separating funnel (S_1 in figure) is now opened fully. By adjusting the upper stop cock (S_2 in figure) the flow can be regulated to obtain the proper speed of dropping of the antigen emulsion, slow enough to receive the drops into the tubes without spilling out. Having adjusted this, the lower stop cock is closed. The racks holding the test tubes are now held under the delivering pipette, the lower stop cock S_1 is opened, and the racks moved slowly to bring the tubes one after another under the pipette to receive the drops. Into the first row one drop is delivered. Into the second row two drops, into the third row four drops. When the charge of antigen in the pipette is finished, it may be recharged as described above.

Certain precautions are to be observed in the working of the apparatus. All connections should be airtight. The Woulfe's bottle should be completely filled with water and the air space that occurs in the bottle by working the syphon should be kept reduced to a minimum. The stem of the separating funnel should be completely filled with water. To the water in the apparatus, some antiseptic may be added to prevent the growth of algae, for only very small quantities of water are wasted whenever the apparatus is worked, and the water need not be replenished for some weeks.

The apparatus is very simple, accurate and labour saving. It can be fitted up in any laboratory and requires very little practice to work.

THE RARITY OF THE MALE *ENTEROBIUS VERMICULARIS*

By P. V. GHARPURE, M.D., D.T.M. & H.
Professor of Pathology, Grant Medical College
and

V. V. GHARPURE, M.B.B.S., B.Hy.
(From the Pathology School, Grant Medical College)

IN the progress of an investigation we were struck by the frequency with which we encountered male threadworms; this tempts us to write this short note. Many books mention that the male threadworms are 'rare', are 'infrequently found', are 'fewer', etc., clearly indicating that they are rarely seen. Our investigations have been confined to the vermiform appendix. We are publishing separately our findings in respect of different aspects of the condition of the vermiform appendix.

The material for investigation came from two sources:—

- (1) From the operation theatre.
- (2) From the post-mortem room.

The frequency of male threadworms has been noted.

The technique followed is as follows:—

As soon as the body is opened the appendix is lifted by gently holding its tip, the mesentery is separated, and a tight ligature tied round its broad receding base. It is then received in a Petri dish. It is slit open along the mesenteric attachment. The contents are carefully viewed. The female threadworms are a contrast to the males in every respect—they are straight with sharp-pointed extremities, opaque white and comparatively rigid. These give the clue to the material being useful for investigation. Small particles of faecal contents are then carefully emulsified in clear saline and tiny transparent hooked small mucinous objects are picked up by sucking fluid by pipettes. These invariably turn out to be male threadworms. We have not failed so far in finding males in any specimen. The numbers in some have been large. In one appendix we found over 12 males in only part of the contents. In that case the bowel contents had shown 36 females. We have not investigated in the same manner stools or intestinal contents from post mortems. It is our impression that the characters of the threadworm are probably more responsible for the reported rarity. They are very tiny, transparent, and often embedded in faeces. In one appendix we found three males coiled together in one faecal clump of the size of a loopful. The male worms are further very fragile.

We are venturing to publish this note in order that other workers in the post-mortem room may confirm our observations.

SERUM COMPLEMENT IN RELATION TO VITAMIN-C DEFICIENCY IN GUINEA-PIGS

By R. K. CHAKRABORTY, M.Sc.
Lady Tata Memorial Scholar
(Indian Institute for Medical Research, Calcutta)

MARSH (1936) observed that the complement titration values of the serum of guinea-pigs decreased very considerably when vitamin C was withdrawn from the food of the animals. When diets rich in vitamin C were supplied to them, the concentrations of the complement in the serum came up to the original values and sometimes even higher. Marsh concluded that vitamin-C deficiency causes a marked fall in the concentration of serum complement.

It seemed to us of interest to investigate this serological problem further in relation to the studies on the biochemical function of vitamin C with which we are engaged. After this work had been completed, a paper by Zilva (1936) appeared in which he was unable to confirm the results of Marsh. Our experiments were planned somewhat differently. It was observed by Guha and Ghosh (1935) that the guinea-pig embryo in the early stages of its development could apparently synthesize vitamin C, an observation which was in accord with the findings of Bourne (1935) that pregnant guinea-pigs get scurvy more slowly than non-pregnant guinea-pigs, when they are placed on a scorbutic diet. Accordingly, we wished to study the changes of serum complement, if any, in vitamin-C deficiency in relation to sex and to the state of pregnancy. Thus, three groups of guinea-pigs consisting of male, female (non-pregnant) and female (pregnant) were chosen. The titration values of the complement of the guinea-pigs were obtained when the animals were on normal diet (gram and green grass). Then each guinea-pig was fed on a scorbutic diet containing 80 per cent gram and 20 per cent oats for a period of 12 days and 2 mg. of pure ascorbic acid were fed daily during this period and then their complement values were determined. The animals were then placed on the scorbutic diet alone for a period of 20 days and the complement titration values of each guinea-pig were determined on the 12th and 20th days, after their being put on this scorbutic diet.

Before proceeding with the titration of the complement, the hæmolysin unit was first determined every day and two units of hæmolysin were used in the titrations of the complement. The serum of the guinea-pigs, for the complement estimation, was made into different dilutions such as 1/4, 1/6, 1/8, 1/10, etc., up to 1/40 and 0.3 c.cm. from each dilution was taken at the time of experiment.

In these titrations the hæmolytic system in each tube consisted of:—

- (a) Red blood cells (sheep's)—0.5 c.cm. of 2 per cent suspension.

(b) Hæmolysin used—0.5 c.cm. of two units.
(c) Serum (of which the complement was to be determined)—0.3 c.cm. of different dilutions.

One c.cm. of normal saline was added to each of the tubes so that the final volume in each case was 2.3 c.cm. The tubes were then incubated on a water bath at a temperature of 37°C. for half an hour and the values were noted. Control experiments were made side by side with (1) sheep's cells *plus* hæmolysin, (2) sheep's cells *plus* saline and (3) sheep's cells *plus* complement but no hæmolysis occurred in these control tubes.

The following table shows the dilutions of the serum where complete hæmolysis took place when the guinea-pigs were kept on different diets :—

Serial number	(a)	(b)	(c)	(d)
	When the animals were on normal diet	After 12 days feeding of 2 mg. of ascorbic acid <i>plus</i> vitamin-C deficient diet	After 12 days on vitamin-C deficient diet	After 20 days on vitamin-C deficient diet
<i>Male guinea-pigs</i>				
1	1/10	1/10	1/10	dead
2	1/20	1/20	1/16	1/16
3	1/8	1/8	1/8	dead
4	1/20	1/20	1/20	1/20
5	1/20	1/20	1/20	1/16
6	1/20	1/20	1/20	1/20
<i>Female (pregnant)</i>				
1	1/16	1/16	1/16	1/16
2	1/10	1/10	1/10	1/10
3	1/8	1/8	1/8	1/8
4	1/8	1/8	1/8	1/8
5	1/16	1/16	dead	dead
6	1/5	1/5	dead	dead
<i>Female (non-pregnant)</i>				
1	1/8	1/10	1/8	1/8
2	1/10	1/10	1/10	1/10
3	1/10	1/10	1/10	1/10
4	1/10	1/10	1/10	1/8
5	1/8	1/10	dead	dead
6	1/5	1/5	dead	dead

The results indicate that in each batch of six guinea-pigs, there is a slight reduction of complement only in two cases among the males, only in one case among the non-pregnant females and in no case among the pregnant females. It appears, therefore, that in vitamin-C deficiency the serum of guinea-pigs hardly suffers a reduction of the complement; nor is there any material sex-difference in this respect.

My thanks are due to Drs. B. C. Guha, J. C. Ray and H. Ghosh for advice and help.

THE PROTEIN AND MINERAL VALUES OF SOME COOKED BENGALI DIETS

By J. C. PAL, M.Sc.

and

B. C. GUHA, Ph.D., D.Sc.

(Indian Institute for Medical Research, Calcutta, and University College of Science, Calcutta)

DURING recent years much attention has been concentrated on the nutritional level of large communities and on the nutritive values of diets consumed by them. Work has chiefly proceeded on three lines—(1) the measurement of the physical indices of the nutritional conditions of the people, (2) the measurement of the prevalence of deficiency diseases, and (3) the estimation of the food values (mainly protein, mineral and vitamin values) of the diets as indicated by their daily or monthly purchases of raw food materials. The deficiencies so ascertained have been sought to be remedied by incorporating in the diets foodstuffs, whose nutritive values, again, have usually been determined in the raw state. Sir John Orr (1936), for instance, has recently published an instructive monograph in which the consumption of essential food ingredients by sections of the British people has been computed from a survey of their budgets concerning the purchase of raw foodstuffs. It would appear that, while such estimates are very useful, more precise and practical information would be obtained if the actual cooked diets, as they are consumed, are evaluated with regard to their nutritive values. Cooking would doubtless alter the food values considerably.

Sir Robert McCarrison's pioneering work in this direction concerning the growth-promoting values of diets consumed in different provinces in India, as determined by the growth of rats, first drew attention to the defects of some of these diets. Guha's results (1934), obtained with the cooked diets obtained from a middle-class young men's hostel in Calcutta, also pointed to partial vitamin-A and -B deficiency in these diets. In this connection, it should be mentioned that, recently, results obtained with experimental animals have, with a certain degree of justification, been criticized with regard to their applicability to the human. On the other hand, it should be realized that metabolic experiments on the human, unless they are carried out with a reasonably large number of subjects, which it is difficult to do for obvious reasons, are apt to be very misleading, owing to the great individual variations

(Continued from previous column)

between man and man. With experimental animals, however, a large number of experiments can be carried out and the results are comparable among themselves. Both methods are open to criticism, but the more reliable method would seem to be to use experimental animals and then to check the results with human subjects. Thus, the value of milk as an article of diet has long been established with experimental animals and Corry Mann's extensive experiments (1926) on the feeding of milk to the young people in educational institutions in Great Britain have confirmed this idea.

In the present work we investigated the protein, calcium, phosphorus and iron contents of the cooked diets consumed in (1) seven middle-class Bengali families in Calcutta, (2) two hospitals and (3) two students' hostels attached to Colleges, in order to obtain information about the intake of these essential dietary constituents in average families, hospitals and hostels. Although it is generally recognized that the diet of the Bengalis is relatively poor in protein and perhaps also in some minerals, precise analytical data concerning the cooked diets are lacking. The present paper is in the nature of a preliminary report and more extensive investigations are in progress.

EXPERIMENTAL

The different items of the cooked diet were taken in the proportions of rice 100 g., dāl (aqueous decoction of pulses) 25 g., fish curry 15 g. and vegetable curry 20 g. These are the proportions in which these items are taken by middle-class people in Bengal. These were mixed up intimately in a dish; aliquot portions (3 to 5 g.) of this mixture were taken for protein estimation and the remainder was dried in an air oven at 100° to 105°C.

The protein content was estimated by the usual Kjeldahl's method of estimating nitrogen and by multiplying this value by the factor 6.25.

For the estimation of iron, calcium and phosphorus, the above dried diet mixture was ignited in a silica crucible and turned to ash completely. The ash was taken up in dilute hydrochloric acid and any insoluble residue was filtered off. The filtrate was made up to a known volume.

Aliquots of this solution were used for the determination of iron, calcium and phosphorus.

Estimation of iron.—Iron determination was carried out by the method of Elvehjem (1930). Ten c.cm. of the above solution were taken, made distinctly alkaline with 40 per cent sodium hydroxide (iron-free), and boiled for an hour. This was cooled, made acid with dilute hydrochloric acid and diluted to a volume of 50 c.cm. The colorimetric estimation was then carried out as outlined by Kennedy (1927). One c.cm. of the standard iron solution equivalent to 0.1 mg. of iron was mixed with 5 c.cm. dilute hydrochloric acid and diluted to 50 c.cm. Aliquot portions (10 c.cm.) of the standard and of the unknown were placed in stoppered cylinders, 10 c.cm. of amyl alcohol and 5 c.cm. of 20 per cent

potassium thiocyanate were added in each cylinder and the mixture was thoroughly shaken. The coloured layers of amyl alcohol were then compared in a colorimeter.

Estimation of calcium.—A known volume of the ash solution was made just alkaline with ammonia, excess of 20 per cent ammonium acetate (10 c.cm. to 15 c.cm.) was added to it and the solution was freed from phosphates by means of dilute ferric chloride. This was filtered and washed with 1 per cent ammonium acetate. The filtrate and washings were boiled with 2 to 3 g. ammonium chloride. One to 2 g. of oxalic acid crystals were added to the boiling solution with continual stirring, a few drops of strong ammonia and a sufficient quantity of 3.5 per cent ammonium oxalate solution were added while the stirring was continued. The precipitate of calcium oxalate was filtered, washed free from chloride with 1 per cent ammonium oxalate solution and burnt to calcium oxide in a silica crucible. The above method was adopted from that of Richards, McCaffrey and Bisbee (1901). The calcium was calculated as calcium oxide.

Estimation of phosphorus.—The method adopted was that of Burns and Henderson (1935). An aliquot portion of the ash solution was taken; 5 c.cm. to 10 c.cm. of concentrated nitric acid were added to it, which was followed by 20 c.cm. to 30 c.cm. of 34 per cent ammonium nitrate solution and finally 70 c.cm. to 80 c.cm. of 3 per cent ammonium molybdate solution were added. The solution was heated and the precipitate of ammonium phosphomolybdate allowed to settle. The precipitate was filtered and freed from acid by washing with hot water. The precipitate was then dissolved in a known volume of 0.5 N sodium hydroxide solution and the excess of alkali titrated with 0.5 N hydrochloric acid, phenolphthalein serving as indicator. One c.cm. of 0.5 N sodium hydroxide was equivalent to 0.675 mg. of phosphorus.

In the two principal meals, Bengalis generally take the same diet and in this work it was assumed that they take the same quantity also. The Bengali middle-class adult was thus supposed to take 1,480 g. in the two principal meals (Guha, 1934). The total quantities of iron, calcium, phosphorus and protein were calculated as they were present in this total quantity of 1,480 g.

The refreshments, tea, milk, etc., taken in addition to the principal meals, were not taken into account.

The quantities of iron, calcium, phosphorus and protein consumed per day by an adult are given in the table.

Discussion

The figures given in the table show that the consumption of these dietary constituents by an average adult per day is comparable among the middle-class families, hospitals and hostels in Calcutta. Stiebeling (1933) of the Government Bureau of Home Economics, U. S. A., gives standard figures for consumption per head per day as follows: protein 68 g.; calcium oxide 1.21 g.; phosphorus 1.23 g.; iron 13 to 14 mg. Comparing the mean values of the family, hospital and hostel diets obtained in the present set of experiments, viz, protein 56.26 g.; calcium oxide 0.89 g.; phosphorus 1.10 g.; iron 55.6 mg.; it would appear that, so far as the present figures go, the consumption of iron is more than optimum, while the consumption of calcium is

TABLE

Family number	Days	Iron in mg.		Calcium oxide in g.		Phosphorus in g.		Protein in g.

about 25 per cent lower and of phosphorus slightly lower. The consumption of protein is also lower and, when it is considered that the bulk of the protein again is derived from vegetable sources, a deficiency in the consumption of adequate amounts of protein of high biological value is indicated. It should be stated that though the consumption of iron appears to be high, it is not clear what proportion of this is present in the assimilable form. It should, however, be remembered in this connection that Stiebeling's standards might quite conceivably be inapplicable to India. But, although there has been discussion on the subject, the actual standards applicable to Indian conditions have not yet been worked out.

Summary

Analyses have been carried out of the cooked diets consumed in seven middle-class families, in two hospitals, and in two hostels in Calcutta. The results are remarkably similar among these three groups. A comparison of

these figures with Stiebeling's standard figures indicates a low consumption of calcium and of protein of good biological value in the present observations. On the other hand, the consumption of iron seems to be higher than the standard value and that of phosphorus only slightly lower.

A Mirror of Hospital Practice

COMBINED MYOPATHY AND NEUROPATHY

By K. D. MANOHAR, M.D. (Bom.)

(From the Pathology School, Grant Medical College, Bombay)

MYOPATHY is not a lesion commonly met with in the post-mortem room. Although a slowly progressive disease beginning in childhood, myopathy hardly permits its victim to reach such an advanced age as to develop neuropathic lesions of a vascular nature such as were found in the case studied which is the first noted in the pathology school, Grant Medical College, since 1920.

A male, aged 45, was brought to the hospital, emaciated, unconscious and with spasm of the right side of the body. No history could be obtained. The head was asymmetrical, the left side of the chest, arm and forearm were shrunken and there was an old fracture deformity of radius and ulna. The hand was in a good state of nutrition, there being no atrophic changes.

The right lower limb was 10 cm. shorter than the left, and the calf was 4 cm. less in diameter. The blood vessels were thickened and tortuous; blood pressure was 148 systolic and 96 diastolic. Ophthalmoscopy showed retinal hæmorrhages and choked disc on the right side. The patient died without regaining consciousness.

Post mortem.—The skin of the left upper limb was thinned and parchment-like. Well-marked arcus senilis was present. The blood vessels in the limbs were thickened but not blocked at any part of their course.

The kidneys were granular, red and small. The cut surface showed excess of pelvic fat and narrowed cortex and medulla, and a number of fibrous bands were present.

Heart moderately hypertrophied, the left ventricle showing distinct hypertrophy as well as dilatation. Coronary vessels patent; musculature normal. The whole length of the aorta showed extensive and severe atheroma with plaques of calcification and soft vegetations.

The skull cap was asymmetrical and thickened, the left half being 5 cm. less in circumference than the right, and excess of fluid escaped on opening the dura mater. A bony plate projected into the cranial cavity from the left orbital roof, forming an empty cyst 7 cm. in depth and 3 cm. in height. This space did not communicate with the frontal sinus or the orbit. The left cerebral hemisphere was atrophied and covered with thick and opaque pia-arachnoid. The blood vessels were thin but not obviously obliterated.

The right internal carotid artery showed obvious calcification of the coat and narrowing of the lumen. Extensive recent hæmorrhage had ploughed up the basal ganglia and the capsular region.

The spinal cord, brain stem and cerebellum showed no gross abnormality.

In the face, the orbicularis oculi and oris were dull white in colour but not distinctly yellow nor greasy to the feel. The extrinsic muscles of the eye and the other muscles of the face and tongue were normal. The muscles of the neck were normal, except the trapezius and the sternomastoids. The muscles of the trunk and diaphragm were normal. In the lower limbs there was a fatty mottling of all muscles on the right side, but this mottling was distinct in appearance from the uniform dull white colour of the affected muscles in the upper limbs. The muscles of the right lower limb were also distinctly more greasy than the muscles in the upper limbs or other healthy muscles of the body.

The muscles of the left upper limb had undergone a marked atrophy. The pectorals, rhomboids and serratus anterior could be well defined, but were much smaller than those of the right side and were dull white in colour. The trapezius showed a number of healthy deep brown muscle bundles interspersed with dull white fibres. In the arm only the belly of the biceps had

persisted as a well-defined muscle but it was of dull white colour. All the muscles of the forearm were completely atrophied, but the intrinsic muscles of the hand were well preserved.

The atrophy was less marked on the right side. Some muscles showed healthy fibres alternating with degenerated fibres and all the muscles were well defined. The trapezius, levator scapulae, and serratus anterior had undergone complete degeneration while the latissimus dorsi, rhomboids, supraspinatus and infraspinatus showed partial degeneration. The teres major and minor were healthy and the subscapularis were completely degenerated. The coracobrachialis and triceps showed complete degeneration; the deltoid, biceps and brachialis anterior showed partial degeneration. In the forearm, pronator teres and quadratus, flexor carpi radialis, palmaris longus, brachioradialis, and anconeus had undergone complete degeneration, and the other muscles were normal. In the palm, flexor pollicis brevis, adductor pollicis and short flexor and extensor of the little finger had degenerated, the other short muscles were healthy.

Photomicrograph showing fragmentation of muscle bundles and cellular invasion of sarcolemma.

Histological examination of the muscles showed pale, homogeneous, stained fibres alternating with very large, deeply-stained bundles. The fibrous sheath was prominent and there was a distinct multiplication of nuclei as well as mononuclear and giant-cell infiltration. The more degenerated muscles showed fibrous tissue replacement but fatty vacuolation was not prominent.

Creatine estimation was carried out; the control healthy muscle showed a creatine percentage of 150 mgm. per cent, and the muscles from this case failed to show more than a trace of creatine.

Direct staining for creatine was done by immersing pieces of normal, neuropathic muscles and portions of muscles from the present case, in solution of picric acid in 10 per cent sodium hydroxide. The normal muscle took on a deep mahogany colour, the neuropathic muscle showed a few healthy muscle bundles which took on a deep colour while the muscle from the present case remained pale yellow.

Thanks are due to Dr. Patwardhan, Professor of Biochemistry, G. S. Medical College, for undertaking the creatine estimation, and to Prof. V. R. Khanolkar, Professor of Pathology and Bacteriology, G. S. Medical College, for supplying histological specimens of biopsy material from myopathic patients.

MULTIPLE STONES IN THE BLADDER

By D. K. FAIRBAIRN KHUSRO, M.R.C.S., L.R.C.P.,
M.B., Ch.M., L.M.

*Medical Officer in charge, Lady Dufferin Hospital,
Aligarh, U. P.*

A WOMAN, 65 years old, came to the Dufferin Hospital, Aligarh, from her village, 40 miles off, complaining of difficulty in micturition of a year's duration, and 'falling of the uterus', which she first noticed 5 years previously.

On examination there was found complete prolapse of the uterus with inversion of the vaginal walls. The external os was seen at the tip of the prolapse and a small atrophied uterine body was felt above and behind it. On palpation of the inverted anterior vaginal wall a number of stones of different sizes were felt in the bladder; some appeared to be very large. A sound could not be passed into the bladder further than half an inch, as it seemed to be full of stones, while the prolapsed uterus could not be replaced owing to obstruction by the stones. There was more or less continuous dribbling of foul-smelling urine, which contained albumin and pus.

The patient was aged, feeble and emaciated. Preliminary treatment with urinary antiseptics was carried out. The suprapubic route was found impassable, so an incision was made in the prolapsed anterior vaginal wall into the bladder. A number of stones, seventy-six in all, were removed; they varied in size from a pea to that of a hen's egg, and were phosphatic in character. The largest weighed 1½ ounces and all of them together, 4 ounces.

The uterus was replaced and the wound sewn up in layers. Operation for prolapse could not be done owing to the feeble condition of the patient and the septic state of the bladder. She made a good recovery and decided to return to me for the prolapse operation in the cold weather. In the meantime a ring pessary was inserted to keep the uterus up and the patient allowed to go home.

CARBUNCLE COMPLICATED WITH ERYSIPELAS

By HANS RAJ, M.B., B.S.

Physician and Surgeon, Ferozepore City

R. R., male, aged 60 years, came with a large carbuncle, about six inches in diameter, on the back, on the 10th August, 1936. The carbuncle was covered

with dirty dressings; it was discharging pus and contained large sloughs. The patient had high temperature and complained of weakness. I advised operation, but he refused and went away taking some 'barber's' ointment with him.

He came back after eight days in a moribund condition with extensive erysipelas on the back, shoulders, front of the chest and abdomen. The temperature was high and pulse 128 per minute. The carbuncle was covered with dirty ointment and was still discharging freely.

I injected him at once with antistreptococcal erysipelas serum (Bayer) and prescribed an iron mixture.

The carbuncle was fomented and cleaned with boric compresses. The injections were repeated twice a day and antiseptic dressings and compresses were continued.

The rash began to disappear and the temperature came down in three days. By the end of the 7th day the erysipelas had disappeared, the wound cleared up rapidly and showed signs of healthy granulations. The iron mixture was stopped and Prontosil tablets (Bayer) were given by mouth. The wound healed up without operation more quickly than usual in such cases and the man was discharged cured in a month.

It is interesting to note that the wound, previously unhealthy, full of pus and sloughs and riddled with openings, manifested marvellous recuperative power and dried up quickly, after the erysipelas abated.

A MELANOTIC SARCOMA OF THE ANAL REGION

By NAND LAL BAJAJ, L.S.M.F. (Hons.)

In charge, Civil Dispensary, Barsar, Kangra District

S. R., aged 74, male, was admitted into my dispensary for the following complaints:—

- (i) Frequency of and difficulty in defæcation.
- (ii) Inability to sit down.
- (iii) Discharge of blood and mucus in stools.
- (iv) Frequency of micturition.

These symptoms began about four years ago but the man was relieved of them about 1½ years ago by an operation in this dispensary. The dispensary record showed that a tumour of the rectum was removed successfully but the relief lasted for only about a year.

Local examination.—A blind external fistula with thick hard margins on the left side of the anus was seen. There were a few black granules at the bottom of the fistula. Per rectum, a hard irregular mass chiefly occupying the posterior wall of the rectum and anus could be felt. It was continuous with the hard mass forming the fistula outside the anus. The growth was partly movable from side to side, and bled on examination. Hæmorrhoids were present. The prostate was enlarged and smooth. The inguinal glands were very slightly enlarged, freely movable, discrete and painless. Lumbar glands were impalpable.

Clinical examination of other parts of the body did not indicate any evidence of metastasis.

Under chloroform, after preliminary preparation, the sphincter ani was dilated and the tumour drawn out of the anal orifice and completely excised. It was about the size of an ordinary orange, irregular in shape, hard in consistency and dark purple in colour except a small patch which was black. The piles were ligatured and excised. The tiny mass with a fistula in it located outside the anus was removed as thoroughly as possible.

A fortnight after the above operation a black neoplasm as big as an almond and with three openings

in it developed and had to be cut away with an area of the healthy tissue around it. The growth contained numerous tiny pigmented granules.

Both the tumours were sent for report to the bacteriologist to the Government at Lahore and the report received was 'melanotic sarcoma'.

The operation wounds having healed, the patient was discharged with advice to come to the dispensary from time to time for examination.

The points of interest in this case are the old age of the patient at which sarcoma appeared, non-occurrence of any apparent metastasis, non-involvement of the glands draining the part, the unusual site for sarcoma and lastly its peculiar spread into the rectal region.

A STONE IN THE PREPUCE

By S. K. SHRIVASTAVA, L.M.P.

In charge, State Hospital, Nagod, C. I.

A MALE, aged 30 years, came to the State Hospital, Nagod, on the 13th September, 1936, with the following complaints:—

1. Pain and burning during micturition.
2. Increased frequency of micturition and passage of urine only drop by drop.
3. Pus-like discharge from the organ.

Previous history.—For about four years he has had trouble during micturition and about a year ago he apparently had gonorrhœa with purulent discharge and severe burning pain during micturition. There was inflammation in the prepuce and phimosis.

Present condition.—General health good. There was phimosis and the prepuce was inflamed. On passing a probe into the orifice a hard body could be felt. The patient was prepared next day for circumcision. On slitting the prepuce a concretion about the size of a betel nut and weighing thirty grains was found. Circumcision was completed and a sound passed into the bladder to see if there were any calculi in it, but none could be felt.

The man was given copaiba-sandalwood oil mixture with bromide. On the sixth day after operation the sutures were removed, the wound healed by first intention and the patient was discharged cured on the 25th September, 1936.

My thanks are due to Lieut.-Colonel R. Kharegat, I.M.S., agency surgeon in Bundelkhand, Nowgong, C. I., who very kindly gave me permission to publish the case.

A CASE OF ACUTE INFECTIVE MYELITIS (INFLUENZAL) TREATED WITH MILK INJECTIONS

By B. H. SINGH, M.C.

LIEUTENANT-COLONEL, I.M.S.

Civil Surgeon, Burdwan

R. S. R., a police constable, aged 43 years, was admitted into the Police Hospital, Burdwan, on 18th October, 1935, with a temperature of 101°F.; he gave a history of exposure while on night duty on the 16th. He was discharged on 28th October, but was readmitted on the 6th November, complaining of some weakness in the legs, pain over the bladder region, frequent micturition and constipation. In this, the initial stage of the disease, he had pyrexia (100°F.), headache, malaise, sore throat and numbness with tingling in the lower extremities.

He was transferred to Fraser Hospital, Burdwan, under Dr. G. C. Sarkar, on the 7th November for investigation and treatment. In the second phase of his disease (the pre-paralytic stage) he complained of weakness gradually spreading upwards in both legs and slight weakness of the arms as well. The fever had subsided but retention of urine was noted. This was soon followed by the paralytic stage or stage of actual invasion of the central nervous system, and paralytic phenomena appeared. The localization of the lesion was noted to be in the lower dorsal region. He had by this time lost all motor functions of the lower limbs, but he could raise his hands and move his arms. The upper part of the body was quite free from paralysis. The palate, the pharynx, the larynx, and the grip of the hands were all unaffected. There was slight loss of sensation to pin prick and light touch tests in both legs, and an indefinite hyperæsthetic zone corresponding to the lower dorsal region was present (girdle pain). The knee and ankle reflexes were exaggerated and Babinski's extensor response was positive. The triceps and biceps reflexes were either normal or slightly exaggerated. The Wassermann reaction was negative. The blood count showed moderate leucocytosis—12,000 per c.mm., polymorphonuclears—75 per cent, small mononuclears—18 per cent, large mononuclears—6 per cent, eosinophils—1 per cent and other cells nil.

Treatment.—The patient was put in a soft bed and proper precautions were taken to avoid the development of trophic lesions such as bed-sores. He was catheterized every 8 to 10 hours, and an enema given daily for constipation, as a routine. When evidence of cystitis appeared, urinary antiseptics, neotropine, urotropine, etc., were administered and a bladder wash with permanganate of potash lotion given. Potassium iodide in moderate doses was given a trial, but the patient took an unfavourable turn. He was showing signs of increasing toxæmia and becoming drowsy with moderate pyrexia (100°F.). By this time, and in spite of strict vigilance, bed-sores appeared, and the patient was rapidly going down hill and was in a very serious state.

At this stage it was decided to try non-specific protein therapy by milk injections. The initial dose of 3 c.cm. was given intramuscularly into the buttock on the 18th November, i.e., 11 days after admission into the Fraser Hospital. The first injection made no appreciable change, and a second injection of 5 c.cm. was given three days later. The bladder irrigation was kept up, but the other accessory treatments were all omitted. The response after the second dose was somewhat encouraging; he could now feel fullness of the bladder—certain evidence of return of the vesical reflex. Encouraged by this a third injection of 5 c.cm. was given after three days, and it was noted that he could slightly move the toes. The general outlook also was brighter, the toxæmic signs were less obvious than before, and except for the re-active rise of temperature after the injections, the temperature was now normal. A fourth injection was given, and after this the bladder showed a return to voluntary power and catheterization was no longer necessary. The treatment was continued and he gradually regained the power of his legs, his bed-sores healed and the girdle pain also subsided. Seventeen days after the first milk injection the patient could move his lower limbs. He was discharged on the 25th December, 1935, when he had just regained enough strength to stand with the help of sticks, as his people were very anxious to take him home.

The total quantity of milk administered in this case was about 33 c.cm. in 7 injections; all were given intramuscularly at intervals of 3 or 4 days. He was given 8 months' sick leave and when he returned from home in September 1936, he looked fit, but said that he still felt a little stiffness in his legs and could not run. He could, however, walk well, and sit and stand normally.

Milk therapy is much used in the Fraser Hospital, Burdwan, and my results in the reduction of malarial spleens have been recorded in the *Gazette* in September 1933. It has also been tried in several other conditions, with good results but we had never before tried it in a disease of this nature. This case is reported in order to draw attention to the possibility of using milk to raise the natural resistance of patients when their condition appears hopeless and they have failed to respond to ordinary treatment.

OSTEOMALACIA; TORSION OF THE PREGNANT UTERUS

By S. MOHD. ANWAR

Jubil Hospital, Amritsar

Case report.—A woman, aged 26, small and ill-developed, was delivered of a full-term child by Cæsarean section.

Previous history.—When a girl of twelve, she had a fall and has never walked properly since then. She was married at the age of fifteen and was delivered of a child by Cæsarean section three years later. She has had severe osteomalacia since then.

On examination it was found that both arms had been broken (*see figure*) and that the pelvis was so

distorted that natural delivery was impossible, so Cæsarean section was performed upon her for the second time. The uterus was long and narrow and the usual incision was made through what was taken to be its anterior surface, but after successful delivery of the child and on proceeding to sew up the incision it was found that the organ was twisted so that the scar of the previous operation was situated behind. On account of the impossibility of natural delivery ever taking place the woman was sterilized. She made a good recovery and the child appeared quite normal.

I wish to thank Lieut.-Col. Padaya, I.M.S., who was in charge of the case, for permission to publish this report.

Indian Medical Gazette

JANUARY

MILK

THERE is no fact so obvious that it cannot be repeated again and again without advantage to someone, as, in a world where values are continually changing, even into the minds of the most balanced, doubt must always manage to creep sometimes. Further, there are writers and teachers with a paradoxical type of mind who consider that to repeat a truth is commonplace but delight in contradicting the teachings of established custom; these dangerous influences have to be counteracted continuously. No truth has been so firmly established by long human experience and so completely confirmed by recent scientific investigation, is so obvious and yet seems to need so frequent repetition as that which is contained in the sentence quoted from the League of Nations' Report on the nutrition problem—'milk is the nearest approach we possess to a perfect and complete food, and no other single food can be used as a substitute'.

Milk not only contains protein, fat and carbohydrates in very suitable proportions for human food but in each instance the nutritive constituent is in an ideal form for easy assimilation. Caseinogen, which is the most important of the milk proteins, the total of which amounts to about 3 per cent, is a protein of high biological value in a condition of almost perfect solution. The carbohydrate constituent (4 to 5 per cent) is lactose, which has the useful property of not being sweet so that it does not tire one by its insipidity, and of withstanding the action of yeasts longer than most sugars. The fat (3 to 4 per cent) in milk is in the form of an extremely fine emulsion which makes it particularly easy to digest.

Milk contains a sufficient quantity of the essential metals, the only exception being iron which is present in very small amounts. Finally, the vitamins A, B, C and D are all represented; vitamin D is present in 'summer' milk in large quantities but 'winter' milk is poor in this substance (in this country the vitamin-D content is nearly always high), and the vitamin-C content is also low and this vitamin is readily destroyed by boiling, but vitamins A and B are present in adequate quantities. That is to say, with the addition of iron, milk provides a diet of high nutritive quality with all the constituents that recent nutritional investigation has shown to be necessary for health, and, thus, science has confirmed a conclusion to which centuries of human experience had already led us.

Probably the most striking tribute that can be paid to milk as a food is its survival as a

substance of primary importance in the human dietary during the pre-bacteriological days when it was rightly considered as a prime factor in the spread of epidemic diseases. Even to-day when we do know how to negate its potentialities as a disease carrier, it provides more problems to the sanitarian than any other article of food. It is an ideal medium for bacterial propagation, far better than water on account of its nutritive properties and far better than other equally nutritious foods on account of its fluid consistency. Nearly all the problems connected with milk arise from its distribution to the consumer after it leaves the udder of the cow, and laws connected with milk are framed to protect the consumer not only from being supplied with contaminated milk but also from being cheated by dilution of the milk by the addition of water.

The laws that have been introduced in many countries, England for example, have been very necessary and have achieved the object of ensuring that the consumer gets an uncontaminated milk of good quality, but there has been another side to the picture. Twenty-five years ago Sir Henry Newman, in a lecture to students at St. Bartholomew's Hospital, remarked that he viewed with concern the increasing load of laws and regulations applied to milk, because, he said, it was causing, and would cause (and, we can now say, has caused), a rise in the price of milk so that the poorer classes would be unable to afford to purchase it. The present-day public health tendency is, without in any way lessening the stringency of the regulations, to make them easier to work, and by means of marketing boards to keep the retail price of milk at a low level without making its production economically unsound to the dairy farmer; that is to say, the nutritional rather than the bacteriological aspects of milk are receiving the greater attention.

The problem in India is of course a different one. In England, even in the rural areas distribution is the main difficulty, whereas in India this is only of importance in a very small percentage of the population, as even in towns a cow is often kept in the well-to-do households. The problem in India is the supply itself, which at less than 3 ounces *per capita* is about a quarter of that of Great Britain and one-sixth that of the United States, not so much on account of the shortage of cattle but on account of their poor quality and, in many parts of India, of the shortage of suitable grazing.

His Excellency the Viceroy has given a much-needed stimulus to the milk-supply problem by importing bulls of good milk-producing strains and thereby trying to raise the quality of the cattle in India. If his example is followed, as we hope it will be, one aspect of the problem will in time be solved; but, as the Viceroy himself has pointed out, it is useless to improve the breed of cattle unless they can be provided

with adequate food for their nourishment and this is a problem that is exercising the minds of agricultural experts in all parts of India to-day. There is apparently very little prospect of extending to any great extent the grazing acreage but there is much that can be done to improve the quality of the existing grazing and to supplement it by growing suitable fodder crops. Some research work on this subject has been done and, though more requires to be done, a much more urgent need is widespread propaganda to disseminate knowledge that has already been gained.

With that of grazing and fodder, inevitably arises the question of disposal of the enormous

numbers of useless, or nearly useless, cattle that produce about a *pow* of milk a day and eat nearly as much of the available food as those that give ten times as much milk. This latter problem involves religious principles that are very difficult to overcome.

There is here an opportunity for the combined efforts of the departments of medical research, agriculture and animal husbandry to make a great drive during the next few years and to increase the milk supply in this country to a figure more in keeping with India's requirements, as, with a Viceroy who has such special experience and interest in all these subjects, they can count on his whole-hearted support.

MEDICAL INTERFERENCE

By M. O. SCHIMELGOR, M.D. (Moscow)

*European and Indian Nursing Home, Sadir Road,
Peshawar*

THROUGHOUT medical history there has been a struggle between two opposite opinions about the relation between different organs, their reciprocal influence on one another, and their relation through the nervous and hormonal systems. The present level of medical science justifies the belief that the reciprocal influence of organs is effected through the endocrine vegetative system as a whole with the assistance of the psychic. The psychic functions in the process cannot be separated from the functions of the endocrine vegetative system. The method adopted in some countries of blocking the sympathetic nervous system by novocaine is probably based on the fact that novocaine interferes with the functions of the endocrine vegetative system, thereby affecting the cortex cerebri and other organs. In this way the whole organism becomes affected, and particularly so that part of it in which the normal process is for some reason weakened, *i.e.*, its part affected by the disease.

The effect of novocaine is short lasting, but the favourable reaction often sets in only after a few days; therefore we see here not the effect but the after-effect of novocaine.

Every interference with a process of the organism or with the normal inter-relation between organs calls forth a protective reaction of the whole organism. There is no doubt that such reaction is organized by the psychic endocrine vegetative system. The enhanced protective activity of the organism may affect the disorganized functions of the organism (*i.e.*, the illness), and cause the illness to follow a more favourable course. It goes without saying that the intensity of the protective reaction

(both generally in the whole organism and locally in the different organs) and its form depends on many conditions, such as the potency and the kind of the irritant, the place of its application, the nature and acquired qualities of the organism, the measure of stability or instability of the tissues, organs, and organism as a whole.

After the administration of a strong, but not excessive, irritant the protective reaction develops in such a way that the morphological and functional disorganization caused by the irritant disappears, and balance in the functions of the organism sets in again. In a case where previous to the administration of the irritant there existed somewhere in the organism a state of disturbance, the protective reaction, generated by the irritant, may beneficially affect the disturbed area. If, however, the irritant should be excessive, the protective process may prove inadequate, and, consequently, not only may the effects of the irritant survive, but other functions of the psychic vegetative endocrine system and of the organism may become disorganized, and the original disturbance may be accentuated. Such a conception of the reaction of the organism refers to any active therapeutic interference such as milk, serum, operation, etc.

The paradoxical results which sometimes appear after some therapeutic or surgical interferences find their explanation in the protective process described above and generated by them in the organism.

We know that in cases of angina pectoris the removal of the third sympathetic knot has beneficial results for the patient, though it has been proved by experience that this knot is the centre of the nerves dilating the arteria coronaris. What then is the reason for the effect of the operation? The whole of the psychic vegetative endocrine system reacts to the grave

irritation caused by the operation; the disease in the muscles, nerves and arteries of the heart is subjected to the action of the protective process and an amelioration ensues, in spite of the fact that the centre for dilating the cardiac arteries has been removed; the remaining vegetative endocrine system, as a whole, counteracts the effect of the operation; and in the course of the general reaction of the organism the hormonal action of the various organs is stimulated (as we know, the adrenalin from supra-renal glands, and the hormone-like substances from the striped and cardiac muscle, dilate the cardiac arteries).

The following is a second illustration to our subject. It is known that the hormones of the parathyroid gland set free calcium in the blood, similarly to the adrenalin setting free sugar. Many believe that the disorganization of the functions of the parathyroid gland is responsible for arthritis deformans. Surgeons, therefore, have removed the parathyroid gland in cases of various bone diseases, and have often achieved thereby good results. A certain surgeon of Straasburg, while performing an operation for the removal of the parathyroid gland in a patient suffering from arthritis deformans, was unable to find the gland he sought and stitched up the wound without having removed the gland. The effect of the operation, however, appeared to be the same as if the gland had actually been removed. After that experience the surgeon used to incise the parathyroid gland and sew up the wound, and that operation proved to be just as effective. Here again the powerful irritation was responsible for calling forth a violent defensive reaction in the whole organism, and the general recuperating process affected in its action the existing disorganization in the feeding of bones and joints. Many more examples of similar reactions of the organism can be cited, but the above is sufficient to illustrate our point that improvement is often due to the defensive reaction of the organism and not to the operation, or, to be more accurate, improvement often takes place in spite of the operation (removal of the third sympathetic knot and the removal of the parathyroid gland).

We have seen that a considerable irritation of the vegetative endocrine system, caused either by a physical, mechanical or chemical agency in any part of the organism, produces a general reaction in the organism. It goes without saying that, in the presence of a disease in the organism, this reaction may lead either to an improvement in the course of the disease, or to a deterioration, or else have no marked effect on it at all, according to the conditions of the organism, to the nature of the disease and the kind of the irritation.

We are inclined to think that in the instances quoted above the effect, in addition to the surgical action, was due to a considerable degree

to the psychological factor as well. Often the general protective reaction of the organism described above is generated by the injection of certain substances, milk, water, etc.

It has already been mentioned above that various effects which may follow the protective reaction of the organism are dependent on the state of the organism, its acquired and inherited peculiarities, the nature of the medical interference, etc. There is, however, a specific peculiarity attached to protective reactions, *viz*, the medicine does not act when it enters the organism and its cells, nor even when it is in the cells, but after leaving them. Actually, when a medicine, an alien matter in the organism, calls forth a protective reaction, that reaction reaches its full vigour of reconstruction after the medicine has left the cells of the body and the organism in general. As the reaction does not stop with the ejection of the medicine but continues for a considerable time, the organism, and particularly the diseased organ, has the chance of wholly concentrating on re-establishing the functions affected by the disease. When a medicine is repeated, every subsequent dose calls forth again a general reaction of the organism, directed primarily to the ejection of the irritant. It is clear that after a number of repetitions of a medicine, particularly in large doses, the protective powers of the organism may be considerably weakened, and consequently the protective reaction may prove inadequate; this should always be kept in mind when repeating medicines.

In that case we may notice something similar to an agent of infection which has entered the organism and is spreading. Repeated ingress into the organism of bacterial toxins from the seat of infection, particularly if they enter in large quantity, may, to a larger or smaller extent, interfere with the development of the protective reaction. Therefore it is only after the administration of the medicine has been discontinued that the best conditions set in for the full development of the protective reaction, as well as for the reaction of reconstruction by which the former is followed.

It should not however be forgotten that any therapeutic method of producing a violent reaction contains an inherent danger. As already mentioned above, not every violent reaction that may be called forth will necessarily develop as a protective reaction, and a deterioration may set in in the region of the disease, or even in another region, as a result of the direct pathological action of the medicine. These effects of medicines often remain undetected, and sometimes come to light only after a considerable time. In some cases they are very difficult to establish, and only a very careful scrutiny of the antecedents of the patient, enquiries from him about the state of each organ and its functional peculiarities, both in the past and present, will help to identify the negative effect

of previous treatments on the health and energy of the patient. As an illustration of the negative after-effect of violent medical therapy, the following example may be cited: During a recent epidemic of jaundice in Germany, it was established that those cases in which there had been at some previous time salvarsan treatment had been particularly serious and had shown a great percentage of deaths.

Bearing in mind that the action of any medicine or medical interference actually amounts to the reaction they generate in the organism as a whole, that they may cause serious consequences in the organism, both immediately and in the more distant future, and that therefore we should be able to assess the conditions of the organism as a whole and observe its changes, it would appear that the theoretical and practical medical science has the following questions to solve:—

1. The minute study of the protective reactions of the organism as a whole, consequent on medical interference; the study of the immediate as well as more distant results of such reactions.

2. Practitioners should not be guided only by the action of medicine but also by the individuality of the patient, and should bear in mind the possible reaction of the organism, both immediate and distant.

3. The action of various medicines should be further investigated.

4. The effects of the various therapeutical interferences both on particular organs and on the organism as a whole, *i.e.*, on the co-ordinating system of the organism (vegetative endocrine system and cortex cerebri) should be re-investigated.

THE TREATMENT OF PILES

By H. WILLIAMSON, O.B.E., M.D., F.R.C.S.E., M.R.C.P.
MAJOR, I.M.S.

St. George's Hospital, Bombay

THE ætiology of this 'universal and distressing complaint' which is very common in India is variable and need not be discussed in detail, though heredity, constipation, sedentary habits, child-bearing, middle age and drastic methods of cleaning the anus are all important factors, while in later life carcinoma of the rectum and enlarged prostate must never be forgotten.

On looking at a patient's anus the surgeon cannot help noticing the radially arranged rugæ in the skin: the rugæ, of course, allow the skin to stretch during defæcation. From this simple observation a very important moral can be drawn, namely that all incisions and scars in this region should run parallel with the rugæ, that is in the long axis of the bowel, otherwise stricture will result. Just as the string in a pair of pyjamas holds the trousers up, so will a ring of fibrous tissue round the anus hold the

fæces in, and, for the same reason, it does not stretch.

Internal piles.—A few inches above the anus the superior hæmorrhoidal artery, which is the terminal branch of the inferior mesenteric, divides into two, each branch subdividing. The artery is accompanied by veins, varicosity of which is the cause of internal piles. One might therefore expect there to be an even number of piles, but this is not so, the usual arrangement being an ace-of-clubs formation, one in front and two behind, probably because of the situation of the three bands of longitudinal muscle fibre in the large bowel.

Palliative treatment.—In very mild cases, where the cause is unlikely to persist, plenty of exercise, plenty of fluids, avoidance of alcoholic or other excesses, and the prescription of a teaspoonful of confection of sulphur and senna each night or a tablespoonful of liquid paraffin twice a day will often effect a cure, especially if helped by a local application, of which there are many on the market.

Injection treatment.—This gives good results, and should always be tried when the piles are not inflamed, ulcerated, prolapsed or very large, and when the patient can be kept under observation, in case it needs to be repeated. Apart from these exceptions the only one I know is the hardy Pathan, who generally prefers something more drastic.

Many specula and syringes, usually called by the name of the inventor, have been devised, but the ordinary fenestrated Sim's speculum supplied by government does very well and a small 'Record' syringe with a fine needle is as good as any other. A sterile solution of 5 per cent quinine bihydrochloride with 10 per cent urethane in water gives very good results. It can be had in 2 c.cm. ampoules prepared by Messrs. Parke, Davis and Company, or can be made up in a teaspoon before use. Another good solution is one of 15 per cent carbolic acid in equal parts of glycerine and water.

Method.—With the patient on his left side and his right foot flat on the table so as to abduct the right knee, the well-vaselined speculum is introduced and slowly opened. The surgeon now waits a moment to allow the piles to swell, a process more easily seen with a flashlight. Three main piles are generally visible. The needle of the syringe is now pushed into one of the piles and not more than half a c.cm. of fluid injected, the process being repeated with the other two piles. If there are more than three, only three should be injected at one sitting, and if the operation has to be repeated; three weeks should be allowed to elapse, as this gives time for the injected piles to shrink. If, after injecting a pile, the surgeon decides that the case needs operation, the latter should be deferred; I once tried combining the two and the result was a stricture. External piles should never be injected.

As the rectal mucosa is insensitive, injection is practically painless; in fact, if the patient complains of the puncture the surgeon can be pretty sure he is making it too low down. For a few days after the operation the patient has slight discomfort and a feeling of fullness in the rectum, but this soon passes off.

Clamp and cautery.—The operation about to be described was invented by Dr. Neve of Kashmir, and is done in Quetta and Shikarpur by Sir Henry Holland, to whom, amongst many other things, I am indebted for my knowledge of it. Properly done, it has many advantages. It is practically bloodless, an important factor with an anæmic patient; it is easy, so can be done in out-stations; it is quick, and, above all, it is not likely to be followed by hæmorrhage, recurrence or stricture.

Preparation.—The morning before the operation the patient is given an ounce of castor oil with 20 minims of tincture of opium and kept on a light diet; the evening before operation he is given a further 10 or 15 minims of tincture of opium with a drachm of tincture catechu, and next morning, about two hours before operation, a soap-and-water enema.

Anæsthetic.—Half a cubic centimetre of stovaine (Barker's solution of 10 per cent stovaine in 5 per cent glucose solution in distilled water) is injected through a lumbar puncture with the patient sitting up. This gives perfect anæsthesia and relaxation, but is apt to be followed by severe headache if much cerebrospinal fluid is allowed to escape. Stovaine takes about ten minutes to become 'fixed', so the patient's head and neck should be kept above the pelvis for that time, after which it does not matter. If for any reason a spinal anæsthetic cannot be given, any general anæsthetic will do, but the patient must be watched when the anus is stretched, as he is apt to stop breathing if not properly under. Local anæsthesia is difficult for the inexperienced and is usually accompanied by poor relaxation of the sphincter.

Instruments.—A Neve's pile clamp and three iron cauteries (see figure 1), three or four pairs of Kocher's forceps, and a pair of scissors curved on the flat are all that is required. The clamp is like a pair of carpenter's pincers with curved blunt edges and a screw to screw it tight, and the cauteries are small pokers with a wooden handle, and a ball on the end which fits easily inside the blades of the clamp.

THE OPERATION

Step 1.—The operator gently but firmly stretches the sphincter with his gloved and vaselined forefingers or thumbs.

Step 2.—The piles are seen to swell and may partly prolapse.

Step 3 (figure 2).—Each pile is caught with a Kocher's forceps, the tip of which points to the centre of the anus.

Step 4.—Neve's clamp is applied, care being taken that its jaws point to the centre of the anus.

Step 5 (figure 3).—Each pile is snipped off with a pair of scissors curved on the flat, the Kocher's forceps remaining attached until the pile is removed.

Fig. 1.—Neve's clamp and cautery.

Fig. 2.—Seizing the pile.

Step 6 (figure 4).—The raw edge of the pile is well cauterized, the clamp being held away from the peri-anal skin so as not to burn it.

Step 7.—The clamp is unscrewed and gently opened, after which it is dipped in cold lotion to cool it before the next pile is treated.

Step 8.—The other piles are dealt with in the same way.

Step 9.—A suppository containing one grain morphia is gently inserted into the rectum, followed by a wick of vaselined gauze to prevent adhesion between the opposite sides. Large tubes or rolls of gauze should be avoided as they separate the cauterized edges and lead to bleeding.

After-treatment.—The patient is kept in bed for ten days, the bowels being opened on the fifth day: the best aperient is a dose of castor

oil, followed in four hours by an enema of equal parts of hot soapy water and olive oil.

Fig. 3.—Cutting off the pile.

The above operation is suitable for most cases, and I have used it successfully even when the piles were prolapsing, but it must never be used for external piles. Those who prefer to suture internal piles will find the method described below for external piles an easy and bloodless one.

External piles.—The 'thrombotic' pile, due to the rupture of a vein, and looking like a small blue grape, can be incised if very painful, and the clot evacuated, otherwise fomentations or an analgesic ointment may be applied.

The other kind of external pile is an extension or relic of an internal one, and varies in constitution from a tag of skin to a vascular mass. The 'three needles' operation, so useful in anterior staphyloma of the eye, is a good way of dealing with the condition. Unless internal piles are being operated on at the same time, a local anæsthetic with some adrenalin is injected into the base of the pile, which is then picked up with a pair of forceps. Three (or more, or less) curved needles are now passed through the base of the pile, parallel with the anal ring (see figure 5). The pile, with the needles in position, is now snipped off with a pair of scissors, the needles are pulled right through and the ligatures tied, thus bringing the raw edges together and allowing no time for infection or hæmorrhage. The top stitch should be tied round the upper edge of the stump so as to catch any artery.

Prolapse of the rectum.—A word about the treatment of this condition may be helpful, as

Fig. 4.—Cauterizing.

Fig. 5.—The 'three needles' operation.

the procedures recommended in textbooks on operative surgery are rather formidable. When palliative measures fail the following method will often effect a cure. The surgeon's left forefinger is placed in the patient's rectum, and, guided by it, the needle of a syringe containing 1 c.cm. of rectified spirit is passed up under the mucous membrane from the muco-cutaneous junction for a distance of one to one-and-a-half inches, the prolapse, of course, having been reduced first. Four punctures are made, one in front, one behind, and one at each side, 1 c.cm. of spirit being injected at each, and care being taken not to injure the male bulb or urethra.

A piece of stout silkworm gut, with a large curved needle at each end, is now taken, and

one of the needles passed up inside the rectum, somewhat to one side, for about two inches (less in a child). The needle is then thrust through the mucosa and brought out through the skin lateral to the coccyx. The other needle is similarly manoeuvred on the opposite side and the ends of the silkworm gut emerging through the skin are tied over a piece of gauze, thus slinging the rectum to the coccyx.

When the stitch is removed on the tenth day there may be some sepsis along its track, which is no drawback as it helps adhesions.

Pruritus ani.—If treatment of the apparent cause fails to relieve the pruritus by far the best remedy is a single intensive dose of x-rays given by a good radiologist.

Medical News

PRESIDENTIAL ADDRESS DELIVERED BY MAJOR-GENERAL SIR CUTHBERT SPRAWSON AT THE SIXTH SESSION OF THE MEDICAL COUNCIL OF INDIA, ON 5TH NOVEMBER, 1936

GENTLEMEN,

Your president has not hitherto addressed you on council matters as a whole. In the earlier days of our constitution our progress was necessarily slow and perhaps laborious; but we have now reached a stage when with more rapid development in the present and the prospect of changes in the future it becomes advisable that the president should rehearse from time to time our activities and explain what your executive committee have done and are doing. Your executive committee will be well acquainted with the matters on which I shall comment, and a study of their proceedings, especially those of their meeting last August, will inform council members of their activities; but our council meet seldom, and it will, I believe, be advantageous if I review briefly for the benefit of members some matters of immediate interest.

Before I go further I must express a deep personal regret, which I know is shared by all of you, at the death of Sir Fazl-i-Husain. Sir Fazl had much to do with the formation of this council, for he was the member of the Viceroy's Council in charge of the Department of Education and Health at the time of the passing of the Medical Council Act, and many of you here will recollect his address at the opening of the first meeting of this council in March 1934. His death has cut short a career that was about to offer still further opportunities to his administrative ability.

You will be aware that since the last meeting of our council the General Medical Council of the United Kingdom have recognized for registration the medical degrees of the universities of Bombay, Lucknow, Madras and Patna and that in the case of the first three universities this recognition has retrospective effect since February 1930, so that there is now no break in the continuity of the recognition they formerly received. The date from which the degrees of Patna University may be recognized is now the subject of separate consideration by your executive committee. You will have noted that the General Medical Council have accepted for recognition all those degrees that we have ourselves hitherto approved. It will be for you to consider the sufficiency of the degrees of some of the other universities of British India during the present session.

Since the purpose of this council under the Medical Act of 1933 is to establish a minimum standard of higher qualifications in medicine, it follows that we are deeply interested in the medical curriculum and it is for that reason that our Act gives us powers to require from time to time information about courses of study from every medical institution in British India that grants a qualification included in our schedules. The council have already published their recommendations on courses of study; but you will be aware that the work of the medical student has been the subject of recent discussion in several countries and that it is necessary for us to reconsider the curriculum and consequently our recommendations thereon from time to time and to adopt our advice to improved knowledge and experience. It is not the object of our council to implant a rigidity in the courses nor even to suggest an entire uniformity in the methods of different universities; but with a rise in standards and improvements in knowledge and in opportunities it follows that our recommendations on courses of study require revision. The council last year instructed your executive committee to carry out such a revision and your committee have now done so and have sent their revised draft recommendations to the universities for their opinions and remarks. The inspectors of the council after completion of their inspections at the several universities have submitted a general report on both courses of instruction and examination of the universities as a whole, and a copy of this report, with the remarks of the executive committee thereon, has been supplied to each member of the council. These reports have also been sent to the universities, with the revised recommendations on courses, and when their observations are received your committee will place the matter before you.

Apart from the details of instruction that your inspectors have to investigate it is necessary for them also to see that the number of students attending classes is not too great for the capacity of the teachers or rooms or material provided for their instruction. Overcrowding may be estimated in various ways and no definite standards exist beyond which it may be said that the number of students should not rise. Your executive committee have however adopted one such criterion and have recommended that during his period of medical and surgical inpatient work each student should be continuously in charge of not less than five beds. An enquiry on this point from the universities has shown that already the majority of universities are able to comply with this condition: those who fall short of it have been requested to attain this standard.

oil, followed in four hours by an enema of equal parts of hot soapy water and olive oil.

PRESIDENTIAL ADDRESS DELIVERED BY MAJOR-GENERAL SIR CUTHBERT SPRAWSON AT THE SIXTH SESSION OF THE MEDICAL COUNCIL OF INDIA, ON 5TH NOVEMBER, 1936

GENTLEMEN,

Your president has not hitherto addressed you on council matters as a whole. In the earlier days of our constitution our progress was necessarily slow and perhaps laborious; but we have now reached a stage when with more rapid development in the present and the prospect of changes in the future it becomes advisable that the president should rehearse from time to time our activities and explain what your executive committee have done and are doing. Your executive committee will be well acquainted with the matters on which I shall comment, and a study of their proceedings, especially those of their meeting last August, will inform council members of their activities; but our council meet seldom, and it will, I believe, be advantageous if I review briefly for the benefit of members some matters of immediate interest.

Before I go further I must express a deep personal regret, which I know is shared by all of you, at the death of Sir Fazl-i-Husain. Sir Fazl had much to do with the formation of this council, for he was the member of the Viceroy's Council in charge of the Department of Education and Health at the time of the passing of the Medical Council Act, and many of you here will recollect his address at the opening of the first meeting of this council in March 1934. His death has cut short a career that was about to offer still further opportunities to his administrative ability.

You will be aware that since the last meeting of our council the General Medical Council of the United Kingdom have recognized for registration the medical degrees of the universities of Bombay, Lucknow, Madras and Patna and that in the case of the first three universities this recognition has retrospective effect since February 1930, so that there is now no break in the continuity of the recognition they formerly received. The date from which the degrees of Patna University may be recognized is now the subject of separate consideration by your executive committee. You will have noted that the General Medical Council have accepted for recognition all those degrees that we have ourselves hitherto approved. It will be for you to consider the sufficiency of the degrees of some of the other universities of British India during the present session.

Since the purpose of this council under the Medical Act of 1933 is to establish a minimum standard of higher qualifications in medicine, it follows that we are deeply interested in the medical curriculum and it is for that reason that our Act gives us powers to require from time to time information about courses of study from every medical institution in British India that grants a qualification included in our schedules. The council have already published their recommendations on courses of study; but you will be aware that the work of the medical student has been the subject of recent discussion in several countries and that it is necessary for us to reconsider the curriculum and consequently our recommendations thereon from time to time and to adopt our advice to improved knowledge and experience. It is not the object of our council to implant a rigidity in the courses nor even to suggest an entire uniformity in the methods of different universities; but with a rise in standards and improvements in knowledge and in opportunities it follows that our recommendations on courses of study require revision. The council last year instructed your executive committee to carry out such a revision and your committee have now done so and have sent their revised draft recommendations to the universities for their opinions and remarks. The inspectors of the council after completion of their inspections at the several universities have submitted a general report on both courses of instruction and examination of the universities as a whole, and a copy of this report, with the remarks of the executive committee thereon, has been supplied to each member of the council. These reports have also been sent to the universities, with the revised recommendations on courses, and when their observations are received your committee will place the matter before you.

Apart from the details of instruction that your inspectors have to investigate it is necessary for them also to see that the number of students attending classes is not too great for the capacity of the teachers or rooms or material provided for their instruction. Overcrowding may be estimated in various ways and no definite standards exist beyond which it may be said that the number of students should not rise. Your executive committee have however adopted one such criterion and have recommended that during his period of medical and surgical inpatient work each student should be continuously in charge of not less than five beds. An enquiry on this point from the universities has shown that already the majority of universities are able to comply with this condition: those who fall short of it have been requested to attain this standard.

Another detail of instruction which has exercised your committee is the fact that many, if not most, of our universities do not take sufficient advantage of the great teaching advantages afforded them by a large hospital outpatient attendance. The teaching is sometimes too confined to the wards.

Your executive committee have also been considering the fact that the universities of Bombay and of the Punjab do not prescribe an age-limit for admission to the medical college nor a limit before which a student cannot obtain qualification. A case was brought to my notice where a young man actually obtained degrees of M.B.B.S. and registered them with the Provincial Medical Council before he had reached the age of 21 years. The necessity of preventing such a possibility in future will be brought to the notice of those concerned.

A further question which your committee have under consideration is the conditions in which at certain universities holders of an L.M.P. diploma are admitted to further courses and allowed to sit for examination for an M.B.B.S. degree.

A consideration of the work of the council in the first two and a half years of its existence and of the effects that this work has produced already by improvements in the courses and in details of instruction and examination in several universities and further by leading the medical faculties of these universities to consider several points in our recommendations should bring satisfaction to members of this council. The recognition that has been accorded to medical degrees by the General Medical Council is also a result of the work of this council and our inspectors. Such changes we may regard as direct good resulting from the establishment of this council; but I am still more impressed when I contemplate the amount of indirect benefit that may truly be said to have resulted from the reports of our inspectors and has in several instances brought authorities, both government and private bodies, who are responsible for the maintenance of medical colleges and their attached hospitals, to make improvements costing in some cases large sums of money in order to comply with the recommendations of our inspectors. I need only instance the changes that have occurred or are occurring in colleges and hospitals in Bombay, in Rangoon and in Calcutta in order to illustrate my meaning and, in particular, the increase in the staff and the expenditure of 16 lakhs of rupees on hospital buildings in Vizagapatam. I consider that the council have reason to be well satisfied with their inspectors who have made these reports and have conscientiously performed what must sometimes be a difficult task. Further I consider we may be satisfied with the response that universities on the whole have made to our recommendations and to the criticisms of our inspectors. Criticisms are not always welcome affairs, but, speaking generally, the remarks of our inspectors have been well received and suitable responses made by the universities.

In accordance with section 13 of the Medical Act it is our duty now to enter into negotiations with other countries, especially with those whose degrees are already in our second schedule, so that we shall be able by September 1937 to recommend to the Governor-General in Council what qualifications should in future be included in our second schedule. These negotiations have been commenced by our secretary and your executive committee is informed of them. To some countries, principally those in which Indian Nationals reside in appreciable numbers, but which do not possess medical qualifications of their own, we are making proposals for their recognition of those degrees that are in our first schedule.

You will find a list of these countries in the minutes of the meeting of the executive committee held in last August of which you already have copies. With most of these countries correspondence is still in progress and you will be asked at a subsequent meeting to consider the recommendations of your executive committee

thereon. The usual tone of response from other parts of the British Empire is that these countries are prepared to recognize those of our degrees that receive also the recognition of the General Medical Council, but not to accept other degrees simply because they are in our first schedule. This response is not unnatural and need not cause us any dissatisfaction or diminish regard for our own council. The Medical Council of India is yet young and has to make its reputation abroad as it has already done in this country. We have found also that the General Medical Council is ready to help us and to understand our difficulties and our relationships with that older body continue to be happy.

In accordance with the principles of reciprocity the General Medical Council have sent for our consideration the latest series of reports by their inspectors on the final examinations of the licensing bodies in the United Kingdom. Your executive committee have considered these reports and have drawn the attention of the General Medical Council to various instances where their recommendations do not appear to be observed by licensing bodies, particularly the cases of the Apothecaries Society of London and the Apothecaries Hall of Dublin.

Quite apart from reciprocity the question of the registration or recognition of foreign degrees in India is under consideration by your committee; the point was raised by the Bombay Medical Council in connection with the application for registration by an Indian National possessing an American degree. The Provincial Medical Councils have been circularized as to their opinion on and their present practice in this matter, and when their replies are received the question will come before you with the recommendation of your committee.

These foreign relationships have further implications than may be at first apparent. We are most nearly concerned with French and Portuguese India, because they are parts of this peninsula, and we find there that whatever qualifications a man may possess he cannot practise medicine in those areas unless he be a national of the country concerned, whereas their nationals may practise without restriction in British India. Other countries have adopted a similar protection based not on qualification, but on nationality, and since this is not a question of medical standard this council, however interested, cannot pursue it. I am therefore approaching the Government of India to deal with this difficulty.

Since the last meeting of this council two new provinces of India have come into being. Each will be entitled to representation on the council by a nominated member, and Orissa, which has established a medical register, by an elected representative of the registered graduates. So far members have been nominated by the governments of the two provinces—Lieut.-Col. G. Verghese representing the Government of Orissa, and Lieut.-Col. B. F. Eminson that of Sind, and we welcome them both to our meeting to-day.

Something in what I have already said foreshadows the changes that will occur in this council after its first four years. Other changes will be that the council will be called upon to appoint a secretary from November 1937 and to elect a president in March 1938.

I conclude by remarking on the unremitting interest that all members of your executive committee have shown in the matters that come before them and on their unselfish zeal in travelling far to give to your council's questions the great advantage of their expert advice on all that pertains to medical education.

XV CONCILIUM OPHTHALMOLOGICUM

ACCORDING to the decision of the XIV International Congress held in Madrid in April 1933, the next Congress will be held in Cairo, Egypt.

In conformity with the decision of the International Council of Ophthalmology, London, of April 1935, the

meetings will be held from 8th to 14th December, 1937.

The two official subjects of the Congress will be:—

1. Arterial Hypertension of the Retina:
General Introducers .. H. Wagner and Keith.
Reporters .. Bailliart—Clinical and anatomical aspects.
2. Endocrinology and the Eye:
General Introducer .. Snapper.
Reporters .. Von Szily, Von Imre, Jeandelize, Lacarrere and Lo Cascio.

The papers should refer preferably to subjects related to the official themes. Only a certain number of papers may deal with independent subjects, provided that the International Council will pass them previously by reason of their originality and interest. The International Council has taken this decision in order to avoid the considerable accumulation of papers which in past Congresses has made efficacious debating extremely difficult. It has been thought preferable that the number of these should be reduced so that they can be discussed with the necessary fullness.

The Local Organizing Committee request the colleagues kindly to send three typewritten copies of the paper intended for reading together with a résumé of not more than 500 words to Dr. Marx, Secretary of the International Council, not later than 1st April, 1937.

Number and size of lantern slides, if any, should be stated, and whether epidiascopes or microscopes (and, if so, how many) are required for the lecture.

On the occasion of the fifth International Ophthalmological Congress a third edition of the Directory will appear. This Directory will contain data concerning the following subjects:—

1. Names (alphabetically arranged) and addresses of all oculists in the world.
2. Titles and volumes of all periodicals which deal with any branch of ophthalmology.
3. Statements of all ophthalmological associations.
4. Hospitals for eye patients.
5. Establishments or institutions for the blind, sight-saving classes, etc.
6. Statistics regarding blindness.

The Secretary of the International Ophthalmological Council (Dr. E. Marx, Oostzeedijk 316, Rotterdam, Holland) would be glad to learn from you whether there are still other subjects of general interest for oculists which, in your opinion, might be included in the Directory.

Two exhibitions, one scientific and one commercial, will be arranged.

Inscription for membership to the Congress is open for every medical man, and those who desire, will please send their applications to the Secretary-General as early as possible together with the sum of 50 Swiss francs, to cover the fees for subscription. The fees for ladies and other associate members of the congressists' families are 25 Swiss francs per person—those can attend receptions, excursions, etc., but are not entitled to attend the scientific meetings, nor will they receive a report of the proceedings of the meetings.

Further details of the Congress meetings, banquets, trips, etc., will be sent in due time, as well as the abstracts of papers and the identification cards for the reduction of railway and other fares.

A housing committee will take charge of facilitating the accommodation and lodgings of the members and their families during their stay in Egypt.

The work of the Organizing Committee will be greatly facilitated if the members subscribe as early as possible.

Papers intended for reading in the Scientific Meetings should be sent directly to Dr. Marx, Oostzeedijk 316, Rotterdam.

All other correspondence should be forwarded to the Secretary-General, XV Concilium Ophthalmologicum, P. O. Box No. 2001, Cairo, Egypt.

DR. M. TEWFIK,
Secretary-General.

Cairo, April 1936.

INDIAN MEDICAL COUNCIL

LIEUT.-COL. B. F. EMINSON, M.B.B.S. (Lond.), D.O.M.S. (Eng.), I.M.S., Civil Surgeon, and Superintendent, Mental Hospital and Medical School, Hyderabad (Sind), has been duly nominated by the Government of Sind, under clause (a) of sub-section (1) of Section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), as a member of the Medical Council of India.

Current Topics

'Albuminuria' or Proteinuria

By G. A. HARRISON, M.D.

(From the *Medical Press and Circular*, Vol. CXIII, 2nd and 9th September, 1936, pp. 189 and 205)

WHEN the statement is made that there is 'albuminuria', the speaker almost always means that one or more of certain qualitative tests on the urine are positive. Actually these are tests not exclusively for albumin, but for urinary proteins as a group. It follows that 'proteinuria' is a better term, and it has the advantage that the user is reminded that further examinations may be required. Accordingly it is logical, first, to describe the routine tests, and then to consider the precautions necessary in their execution. For reasons which will be discussed, it should be an invariable rule to examine microscopically the urinary deposit whenever protein is found. In practice, after these preliminaries, the clinical findings will dictate the next step, if any, to be taken. At this point the combined evidence will often enable a judgment to be made as to the probable source and nature of the protein or proteins in the urine, but in certain cases

further tests will be necessary for their separation and identification, or, it may be, their estimation. In special cases the medical officer will wish to extend his examination by methods for assessing renal efficiency.

Whilst clearly it is necessary to consider the course, nature, separation, identification and estimation of the proteins, this article is concerned primarily with the practical clinical aspects, so that only the simpler techniques will be detailed, though a few references will be given to more elaborate tests, which would be undertaken in a well-equipped laboratory.

It is generally accepted that a simple chemical examination of the urine, including testing for protein, constitutes an essential part of the routine clinical examination of every patient, whether urinary symptoms are present or not. It is the rule before every operation, and for very many applications, for life insurance. Clearly, therefore, proteinuria is a subject of wide and genuine importance.

ROUTINE QUALITATIVE TESTS FOR PROTEIN

A large number of methods are available for precipitating proteins, as may be appreciated by consulting the textbooks of physiological chemistry, and

it is out of the question in this article to attempt to consider most of them. The writer's selection is based on his experience of those most commonly employed in clinical work, and is limited to three. The boiling and acetic acid test is probably used more than any other; the salicyl-sulphonic acid test has the advantage that no heat is required which is true also for the nitric acid ring test; but the last, though frequently employed, may lead to a number of errors as detailed below.

The boiling and acetic acid test.—Urine is poured into a test-tube up to the two-third or three-quarter line. The tube is inclined, and the top half-inch column is boiled by means of a small flame. A precipitate indicates protein or earthy phosphates. A single drop of acetic acid (about 33 per cent) is added and the boiling is repeated, when phosphates re-dissolve, but protein remains undissolved.

Albumin, pseudo-globulin, and eu- or lipid-globulin are coagulated by heat, and mucus may be thrown out on acidification. Bence-Jones' protein may be precipitated with moderate heat, to re-dissolve on boiling, but resolution may be incomplete or not noted, and the protein may be missed altogether if there has been over-acidification (*see later*).

The initial reaction of the urine is very important and it is a golden rule always to take it with litmus before testing for protein. On heating, carbon dioxide is driven off, and in some cases the resulting shift of reaction towards the alkaline side may bring about a precipitation of earthy phosphates, which are re-dissolved on acidification by acetic acid. The optimum reaction for the precipitation of proteins is slightly acid. If the urine initially is very alkaline—and samples provided for testing fairly commonly are ammoniacal owing to decomposition by bacteria—the boiling may not bring down the protein owing to the formation of alkaline metaprotein. If, however, the boiled mixture is now made just acid to litmus with 33 per cent acetic acid—as much as 5 to 10 drops may be required in some cases—the protein is precipitated, and this may cause surprise. (Metaprotein is insoluble in *neutral or slightly acid* solutions of salts.) This effect of alkaline urine is a practical point, for it may lead to failure to detect proteinuria or to the false conclusion that the 'albuminuria' has cleared up.

Naturally-acid urine is never so acid as to cause failure to detect protein by conversion into acid metaprotein, but it is essential to avoid making the boiled urine grossly acid with acetic acid lest this should happen.

The salicyl-sulphonic acid test is performed by adding to 10 to 12 drops (about 0.5 c.c.) of 25 per cent w/v salicyl-sulphonic (sulpho-salicylic) acid to about 5 c.c. (1-in. column in an ordinary test tube of $\frac{1}{2}$ -in. bore) of urine. Proteins (albumin, globulins, mucus, Bence-Jones' protein, proteoses) give a white precipitate. Whenever there is any doubt as to the existence of a precipitate the treated urine should be compared with untreated urine in another tube held by the side of the first. Another practical aid is to view the two tubes in front of a shaded electric light (*e.g.*, microscope lamp).

Very uncommonly uric acid is precipitated, but is promptly differentiated by warming, when it re-dissolves. Again, the initial urinary reaction is to be remembered, for 0.5 c.c. of the salicyl-sulphonic acid may not be enough for 5 c.c. of urine if the initial reaction be very alkaline. Uroselectan (sodium salt of 5-iodo-2-pyridone-N acetic acid), used for making the urinary tract opaque to x-rays, gives a false positive reaction if administered within the previous six hours. The urine gives a white crystalline precipitate, which may be copious. Differentiation is easy because the precipitate (presumably of the free organic acid) is readily dissolved by adding about two volumes of absolute alcohol and warming.

Heller's nitric acid ring test is performed by superimposing about 3 c.c. ($\frac{1}{2}$ -in. column) of urine on a

similar volume of concentrated nitric acid. A white ring generally indicates protein (albumin, globulins, mucus, Bence-Jones' protein or proteoses), but occasionally may be due to urea nitrate, uric acid, uroselectan, resinous bodies or even bile acids. Urinary pigments or chromogens are oxidized by nitric acid to darker compounds, and when proteinuria is slight the white ring may be obscured by the pigmentation. The protein is changed by the nitric acid into metaprotein, which is insoluble in strong mineral acid.

PRECAUTIONS IN EXECUTION OF ABOVE TESTS— CONTAMINATION OF URINE

Proteinuria may result from contamination of the urine in several ways, particularly in women. Gross admixture with menstrual discharge will be suspected from the red colour of the sample, but lesser grades of contamination in the same way, as also access of a vaginal discharge other than that due to the menses, are frequent causes of slight proteinuria in women. They should be considered whenever proteinuria is accompanied by a quantity of squamous epithelial cells in the centrifuged deposit. Careful local cleansing just before micturition usually avoids this difficulty, when the sample is to be examined by chemical means only, but catheterization is generally performed if the bacteriology is also to be studied.

Fæcal contamination of slight degree seldom interferes in testing for protein; the fæces contain varying amounts of mucus, but only gross contamination is likely to cause trouble.

In males contamination with semen is at times responsible for positive tests for protein; the presence of spermatozoa in the centrifuged deposit gives the clue, and in all such cases another sample of urine should be obtained for test purposes.

The urine may be opalescent or turbid from a variety of causes thus making it difficult to decide whether protein is present, if the urine is not first cleared. In practice all such turbid urines should be filtered, and this will remove turbidities due to suspended phosphates, urates, or to gross pyuria, etc., but it will not invariably clear the urine entirely; in that case the residual opalescence is most commonly due to bacteria, and is seldom so marked as to interfere with subsequent testing by the boiling and acetic acid test, or by the salicyl-sulphonic acid test, provided that a comparison tube be employed as recommended. More elaborate means of clarifying the urine are seldom justified in practice owing to their being so time-consuming.

Occasionally deliberate contamination of the urine, *e.g.*, by milk, may be responsible for positive findings, in which case catheterization will be required. At other times, *e.g.*, in life-insurance work, it may be important that the sample be passed in the doctor's presence.

In conclusion, the macroscopical and microscopical examination of any sediment or suspended matter will usually guard against errors due to contamination.

MICROSCOPICAL EXAMINATION OF URINARY DEPOSIT ESSENTIAL WHENEVER PROTEINURIA IS FOUND

Positive tests for protein should invariably be followed by an examination under the microscope of the urinary deposit, separated by centrifuging, unless the deposit is macroscopic. The first reason for this rule has already been considered above under the heading of contamination, and is obviously of great importance.

The second reason is that it often aids in the interpretation of the positive results, always, of course, in the light of the clinical findings, and may thus assist in deciding from what part of the urinary tract the protein is coming. Thus presence or absence of casts, erythrocytes, leucocytes and various types of epithelial cells, and the approximate quantities present, all are important in assessing the significance of the proteinuria. Mucus can often be recognized under the microscope. It is therefore essential to consider the morphology of urinary deposits in any practical article on proteinuria.

THE FINDINGS ON EXAMINING URINARY DEPOSITS

If a deposit is visible to the unaided eye at the bottom of the urinary receiver, a few drops are sucked up into a test-pipette, and one or two are mounted under a cover slip on a slide, and examined directly under the microscope.

In all other cases about 10 c.c. of the well-mixed urine are centrifuged and the supernatant fluid is carefully decanted completely. On righting the tube one or two drops will drain back on to the deposit, with which they are thoroughly mixed by sucking up into the pipette, and then squirting them out repeatedly in order to detach the deposit and obtain an even suspension, which is then mounted and examined.

It is impossible in the space available to give a detailed description of the great variety of urinary deposits, which are described in the books on clinical pathology, physiological chemistry, etc., but an attempt will be made to outline the general principles, together with some practical items from the point of view of proteinuria. It takes years of experience to reach the stage when every constituent of every deposit can be labelled with reasonable certainty, but a much shorter period is sufficient to learn what to look for, and what is important practically.

Deposits may be conveniently classified under four headings: cells, casts, crystals plus amorphous chemical deposits, and miscellaneous.

Normal uncontaminated urine, examined as above described, contains no red cells, and shows no more than about 20 leucocytes or 20 epithelial cells on the whole slide. One or two hyaline casts may be found, or perhaps an occasional cylindroid (see below) but any other type of cast should, in the writer's opinion, be regarded as pathological unless repeated examination (clinical and laboratory) permits the opposite conclusion (see later, and particularly under 'intermittent proteinuria'). Crystals and chemical deposits most commonly separate from the urine after it has been passed. The only chemical deposits of importance with reference to proteinuria are those in suspension at the moment of micturition, which for this reason should be witnessed by the doctor if possible. In the majority of these cases, too, the chemical suspension does not matter, and is observed fairly often in health, but it is among cases of this kind only that the medical officer may be justified at times in ascribing proteinuria to irritation by crystals.

Red blood corpuscles are very pale-yellow, homogeneous, biconcave discs of about 7μ in diameter. They generally lie flat and show a double contour, best seen by carefully focussing up and down. In urine, however, they may be considerably altered in appearance, either becoming swollen eventually to spheres (hypotonic urine), and so losing their double contour, or becoming shrunken or crenated. They are not as refractile as other cells.

White blood corpuscles are a little larger than the average red cell, about 7 to 10μ in diameter. They are colourless spheres, heterogeneous and granular, and the nucleus may be visible. In urine they may show varying stages of degeneration, and when both degenerated and numerous are often called pus cells.

Epithelial cells vary considerably in size and shape, depending on their site of origin from any part of the urinary tract from the kidneys down to the urinary meatus, or externally. It is important to be able to recognize squamous epithelial cells (see contamination above), but otherwise guesses only can be hazarded as to their origin, because no one type of cell is absolutely characteristic of one particular site. It is true that renal epithelial cells are about the size of leucocytes, roughly polygonal in outline with a well-marked nucleus, but such cells are not invariably derived from the kidney. Cells from the bladder and urethra vary much in appearance and size, depending on whether they are derived from superficial or deeper layers; 'tailed cells' often come from the bladder, but may also originate in the renal pelvis. As a class epithelial cells vary in size (the smallest being of about the diameter of a

leucocyte, the largest being the squamous epithelial cell), vary in shape, are colourless, heterogeneous, often granular and nucleated.

Casts are derived from the renal tubules. Each may be regarded as an internal mould of part of a tubule, and formed by an exudate consisting mainly of protein. When detached and passed down the tract this constitutes the 'hyaline cast' in the urinary deposit. When the inflammatory reaction is more severe the epithelial cells of the tubule are also damaged and detached, and in varying numbers coat, or become embedded into, the surface of the hyaline matrix, so giving 'epithelial casts'. Similarly 'blood casts' are due to the hyaline matrix being coated with varying numbers of red cells. The cells, or possibly the matrix too, often undergo degeneration, giving rise to granules or fatty droplets, and so is formed the 'granular' or 'fatty' cast. As would be expected, all possible intermediate stages between these types are observed, e.g., hyaline, with a few granules, or 'hyalo-granular', granular with an odd epithelial cell recognizable, or 'granulo-epithelial', and so on. Waxy casts are hyaline in appearance, but generally broader, and are fissured; they should not be regarded as necessarily indicative of waxy or amyloid disease of the kidney. Cylindroids look like long narrow hyaline casts, often indeed very long, and are by most authorities regarded as immaterial.

The finding of casts in proteinuria is important in that it points to some at least of the protein as being due to renal damage though the magnitude of the damage must never be hazarded from the urinary findings alone but always after consideration of the clinical findings (see later).

In the miscellaneous group are mucus, spermatozoa (see contamination above), bacteria or yeasts, parasites and foreign bodies. Mucus is present in normal urine in small amounts (see next section), but when in pathological amount it may be responsible, in part or even wholly, for positive reactions with the qualitative tests for protein and in acid urine may be centrifuged down and recognized under the microscope. Its microscopic appearance is difficult to describe but once appreciated recognition is easy; it is in ill-defined smeary streaks or strings.

True bacteria—bacteria in the urine *in vivo*—may or may not be accompanied by proteinuria, depending on the presence or absence of a sufficient grade of inflammation at some point in the urinary tract. In this country parasites (bilharzia, filaria, echinococcus) are a very uncommon cause of albuminuria.

So far no mention has been made of the interesting work of Addis in counting the number of cells and casts in the twelve hours' night urine, because it is too elaborate and time-consuming for routine work. It is mentioned, however, because he does find a certain number of red cells, leucocytes, and even casts in normal urine, and sets a limit for each, above which the finding may be regarded as pathological. Though more accurate and quantitative, Addis's results are not considered to be contradictory to the interpretation given above of the practical rough working method recommended.

THE SOURCES AND NATURE OF URINARY PROTEINS

Normal urine contains no protein other than a minute trace of mucus, which is present in so small a quantity that it does not give a positive reaction with any of the routine qualitative tests. None the less it may become apparent to the unaided eye when a relatively large volume (e.g., 200 c.c.) of urine is allowed to stand undisturbed by its separation as a light flocculent cloud.

Pathologically, proteins pass into the urine either by exudation (plasma-albumin, plasma-globulin and hæmoglobin inside red cells) or by transudation (plasma-albumin and globulins), or through hæmorrhage greater or less, into some part of the urinary tract (plasma-albumin and globulins, hæmoglobin inside red cells, and in relatively gross hæmorrhages, fibrinogen which yields fibrin). Further, the kidneys will allow to pass

it is out of the question in this article to attempt to consider most of them. The writer's selection is based on his experience of those most commonly employed in clinical work, and is limited to three. The boiling and acetic acid test is probably used more than any other; the salicyl-sulphonic acid test has the advantage that no heat is required which is true also for the nitric acid ring test; but the last, though frequently employed, may lead to a number of errors as detailed below.

The boiling and acetic acid test.—Urine is poured into a test-tube up to the two-third or three-quarter line. The tube is inclined, and the top half-inch column is boiled by means of a small flame. A precipitate indicates protein or earthy phosphates. A single drop of acetic acid (about 33 per cent) is added and the boiling is repeated, when phosphates re-dissolve, but protein remains undissolved.

Albumin, pseudo-globulin, and eu- or lipid-globulin are coagulated by heat, and mucus may be thrown out on acidification. Bence-Jones' protein may be precipitated with moderate heat, to re-dissolve on boiling, but resolution may be incomplete or not noted, and the protein may be missed altogether if there has been over-acidification (see later).

The initial reaction of the urine is very important and it is a golden rule always to take it with litmus before testing for protein. On heating, carbon dioxide is driven off, and in some cases the resulting shift of reaction towards the alkaline side may bring about a precipitation of earthy phosphates, which are re-dissolved on acidification by acetic acid. The optimum reaction for the precipitation of proteins is slightly acid. If the urine initially is very alkaline—and samples provided for testing fairly commonly are ammoniacal owing to decomposition by bacteria—the boiling may not bring down the protein owing to the formation of alkaline metaprotein. If, however, the boiled mixture is now made just acid to litmus with 33 per cent acetic acid—as much as 5 to 10 drops may be required in some cases—the protein is precipitated, and this may cause surprise. (Metaprotein is insoluble in *neutral or slightly acid* solutions of salts.) This effect of alkaline urine is a practical point, for it may lead to failure to detect proteinuria or to the false conclusion that the 'albuminuria' has cleared up.

Naturally-acid urine is never so acid as to cause failure to detect protein by conversion into acid metaprotein, but it is essential to avoid making the boiled urine grossly acid with acetic acid lest this should happen.

The salicyl-sulphonic acid test is performed by adding to 10 to 12 drops (about 0.5 c.c.) of 25 per cent w/v salicyl-sulphonic (sulpho-salicylic) acid to about 5 c.c. (1-in. column in an ordinary test tube of $\frac{1}{2}$ -in. bore) of urine. Proteins (albumin, globulins, mucus, Bence-Jones' protein, proteoses) give a white precipitate. Whenever there is any doubt as to the existence of a precipitate the treated urine should be compared with untreated urine in another tube held by the side of the first. Another practical aid is to view the two tubes in front of a shaded electric light (e.g., microscope lamp).

Very uncommonly uric acid is precipitated, but is promptly differentiated by warming, when it re-dissolves. Again, the initial urinary reaction is to be remembered, for 0.5 c.c. of the salicyl-sulphonic acid may not be enough for 5 c.c. of urine if the initial reaction be very alkaline. Uroselectan (sodium salt of 5-iodo-2-pyridone-N acetic acid), used for making the urinary tract opaque to x-rays, gives a false positive reaction if administered within the previous six hours. The urine gives a white crystalline precipitate, which may be copious. Differentiation is easy because the precipitate (presumably of the free organic acid) is readily dissolved by adding about two volumes of absolute alcohol and warming.

Heller's nitric acid ring test is performed by superimposing about 3 c.c. ($\frac{1}{2}$ -in. column) of urine on a

similar volume of concentrated nitric acid. A white ring generally indicates protein (albumin, globulins, mucus, Bence-Jones' protein or proteoses), but occasionally may be due to urea nitrate, uric acid, uroselectan, resinous bodies or even bile acids. Urinary pigments or chromogens are oxidized by nitric acid to darker compounds, and when proteinuria is slight the white ring may be obscured by the pigmentation. The protein is changed by the nitric acid into metaprotein, which is insoluble in strong mineral acid.

PRECAUTIONS IN EXECUTION OF ABOVE TESTS— CONTAMINATION OF URINE

Proteinuria may result from contamination of the urine in several ways, particularly in women. Gross admixture with menstrual discharge will be suspected from the red colour of the sample, but lesser grades of contamination in the same way, as also access of a vaginal discharge other than that due to the menses, are frequent causes of slight proteinuria in women. They should be considered whenever proteinuria is accompanied by a quantity of squamous epithelial cells in the centrifuged deposit. Careful local cleansing just before micturition usually avoids this difficulty, when the sample is to be examined by chemical means only, but catheterization is generally performed if the bacteriology is also to be studied.

Fæcal contamination of slight degree seldom interferes in testing for protein; the fæces contain varying amounts of mucus, but only gross contamination is likely to cause trouble.

In males contamination with semen is at times responsible for positive tests for protein; the presence of spermatozoa in the centrifuged deposit gives the clue, and in all such cases another sample of urine should be obtained for test purposes.

The urine may be opalescent or turbid from a variety of causes thus making it difficult to decide whether protein is present, if the urine is not first cleared. In practice all such turbid urines should be filtered, and this will remove turbidities due to suspended phosphates, urates, or to gross pyuria, etc., but it will not invariably clear the urine entirely; in that case the residual opalescence is most commonly due to bacteria, and is seldom so marked as to interfere with subsequent testing by the boiling and acetic acid test, or by the salicyl-sulphonic acid test, provided that a comparison tube be employed as recommended. More elaborate means of clarifying the urine are seldom justified in practice owing to their being so time-consuming.

Occasionally deliberate contamination of the urine, e.g., by milk, may be responsible for positive findings, in which case catheterization will be required. At other times, e.g., in life-insurance work, it may be important that the sample be passed in the doctor's presence.

In conclusion, the macroscopical and microscopical examination of any sediment or suspended matter will usually guard against errors due to contamination.

MICROSCOPICAL EXAMINATION OF URINARY DEPOSIT ESSENTIAL WHENEVER PROTEINURIA IS FOUND

Positive tests for protein should invariably be followed by an examination under the microscope of the urinary deposit, separated by centrifuging, unless the deposit is macroscopic. The first reason for this rule has already been considered above under the heading of contamination, and is obviously of great importance.

The second reason is that it often aids in the interpretation of the positive results, always, of course, in the light of the clinical findings, and may thus assist in deciding from what part of the urinary tract the protein is coming. Thus presence or absence of casts, erythrocytes, leucocytes and various types of epithelial cells, and the approximate quantities present, all are important in assessing the significance of the proteinuria. Mucus can often be recognized under the microscope. It is therefore essential to consider the morphology of urinary deposits in any practical article on proteinuria.

THE FINDINGS ON EXAMINING URINARY DEPOSITS

If a deposit is visible to the unaided eye at the bottom of the urinary receiver, a few drops are sucked up into a test-pipette, and one or two are mounted under a cover slip on a slide, and examined directly under the microscope.

In all other cases about 10 c.c. of the well-mixed urine are centrifuged and the supernatant fluid is carefully decanted completely. On righting the tube one or two drops will drain back on to the deposit, with which they are thoroughly mixed by sucking up into the pipette, and then squirting them out repeatedly in order to detach the deposit and obtain an even suspension, which is then mounted and examined.

It is impossible in the space available to give a detailed description of the great variety of urinary deposits, which are described in the books on clinical pathology, physiological chemistry, etc., but an attempt will be made to outline the general principles, together with some practical items from the point of view of proteinuria. It takes years of experience to reach the stage when every constituent of every deposit can be labelled with reasonable certainty, but a much shorter period is sufficient to learn what to look for, and what is important practically.

Deposits may be conveniently classified under four headings: cells, casts, crystals plus amorphous chemical deposits, and miscellaneous.

Normal uncontaminated urine, examined as above described, contains no red cells, and shows no more than about 20 leucocytes or 20 epithelial cells on the whole slide. One or two hyaline casts may be found, or perhaps an occasional cylindroid (*see below*) but any other type of cast should, in the writer's opinion, be regarded as pathological unless repeated examination (clinical and laboratory) permits the opposite conclusion (*see later*, and particularly under 'intermittent proteinuria'). Crystals and chemical deposits most commonly separate from the urine after it has been passed. The only chemical deposits of importance with reference to proteinuria are those in suspension at the moment of micturition, which for this reason should be witnessed by the doctor if possible. In the majority of these cases, too, the chemical suspension does not matter, and is observed fairly often in health, but it is among cases of this kind only that the medical officer may be justified at times in ascribing proteinuria to irritation by crystals.

Red blood corpuscles are very pale-yellow, homogeneous, biconcave discs of about 7μ in diameter. They generally lie flat and show a double contour, best seen by carefully focussing up and down. In urine, however, they may be considerably altered in appearance, either becoming swollen eventually to spheres (hypotonic urine), and so losing their double contour, or becoming shrunken or crenated. They are not as refractile as other cells.

White blood corpuscles are a little larger than the average red cell, about 7 to 10μ in diameter. They are colourless spheres, heterogeneous and granular, and the nucleus may be visible. In urine they may show varying stages of degeneration, and when both degenerated and numerous are often called pus cells.

Epithelial cells vary considerably in size and shape, depending on their site of origin from any part of the urinary tract from the kidneys down to the urinary meatus, or externally. It is important to be able to recognize squamous epithelial cells (*see contamination above*), but otherwise guesses only can be hazarded as to their origin, because no one type of cell is absolutely characteristic of one particular site. It is true that renal epithelial cells are about the size of leucocytes, roughly polygonal in outline with a well-marked nucleus, but such cells are not invariably derived from the kidney. Cells from the bladder and urethra vary much in appearance and size, depending on whether they are derived from superficial or deeper layers; 'tailed cells' often come from the bladder, but may also originate in the renal pelvis. As a class epithelial cells vary in size (the smallest being of about the diameter of a

leucocyte, the largest being the squamous epithelial cell), vary in shape, are colourless, heterogeneous, often granular and nucleated.

Casts are derived from the renal tubules. Each may be regarded as an internal mould of part of a tubule, and formed by an exudate consisting mainly of protein. When detached and passed down the tract this constitutes the 'hyaline cast' in the urinary deposit. When the inflammatory reaction is more severe the epithelial cells of the tubule are also damaged and detached, and in varying numbers coat, or become embedded into, the surface of the hyaline matrix, so giving 'epithelial casts'. Similarly 'blood casts' are due to the hyaline matrix being coated with varying numbers of red cells. The cells, or possibly the matrix too, often undergo degeneration, giving rise to granules or fatty droplets, and so is formed the 'granular' or 'fatty' cast. As would be expected, all possible intermediate stages between these types are observed, *e.g.*, hyaline, with a few granules, or 'hyalo-granular', granular with an odd epithelial cell recognizable, or 'granulo-epithelial', and so on. Waxy casts are hyaline in appearance, but generally broader, and are fissured; they should not be regarded as necessarily indicative of waxy or amyloid disease of the kidney. Cylindroids look like long narrow hyaline casts, often indeed very long, and are by most authorities regarded as immaterial.

The finding of casts in proteinuria is important in that it points to some at least of the protein as being due to renal damage though the magnitude of the damage must never be hazarded from the urinary findings alone but always after consideration of the clinical findings (*see later*).

In the miscellaneous group are mucus, spermatozoa (*see contamination above*), bacteria or yeasts, parasites and foreign bodies. Mucus is present in normal urine in small amounts (*see next section*), but when in pathological amount it may be responsible, in part or even wholly, for positive reactions with the qualitative tests for protein and in acid urine may be centrifuged down and recognized under the microscope. Its microscopic appearance is difficult to describe but once appreciated recognition is easy; it is in ill-defined smears or strings.

True bacteria—bacteria in the urine *in vivo*—may or may not be accompanied by proteinuria, depending on the presence or absence of a sufficient grade of inflammation at some point in the urinary tract. In this country parasites (bilharzia, filaria, echinococcus) are a very uncommon cause of albuminuria.

So far no mention has been made of the interesting work of Addis in counting the number of cells and casts in the twelve hours' night urine, because it is too elaborate and time-consuming for routine work. It is mentioned, however, because he does find a certain number of red cells, leucocytes, and even casts in normal urine, and sets a limit for each, above which the finding may be regarded as pathological. Though more accurate and quantitative, Addis's results are not considered to be contradictory to the interpretation given above of the practical rough working method recommended.

THE SOURCES AND NATURE OF URINARY PROTEINS

Normal urine contains no protein other than a minute trace of mucus, which is present in so small a quantity that it does not give a positive reaction with any of the routine qualitative tests. None the less it may become apparent to the unaided eye when a relatively large volume (*e.g.*, 200 c.c.) of urine is allowed to stand undisturbed by its separation as a light flocculent cloud.

Pathologically, proteins pass into the urine either by exudation (plasma-albumin, plasma-globulin and hæmoglobin inside red cells) or by transudation (plasma-albumin and globulins), or through hæmorrhage greater or less, into some part of the urinary tract (plasma-albumin and globulins, hæmoglobin inside red cells, and in relatively gross hæmorrhages, fibrinogen which yields fibrin). Further, the kidneys will allow to pass

any proteins which normally are absent from or foreign to the plasma, or, as suggested by Bayliss, Kerridge and Russell, which have a lower molecular weight (see below), and therefore presumably (but not necessarily) smaller-sized molecules than the normal blood proteins (hæmoglobin which is free in physical solution in the plasma (hæmoglobinæmia), methæmoglobin (and presumably sulphæmoglobin) when extra-corporeal, Bence-Jones' protein, and proteoses). Likewise the kidneys filter off any protein truly foreign to the circulation but artificially introduced by injection, provided, according to Bayliss *et al.*, its molecular weight is below about 68,000.

Proteins which are excreted	Mol. wt.	Protein not excreted	Mol. wt.
Gelatin ..	35,000	Hæmoglobin ..	68,000
Egg albumin ..	34,500	Serum albumin ..	67,500 *
Bence-Jones' ..	35,500	Serum globulin ..	103,800
† Hæmoglobin ..	68,000	Casein ..	188,000

Mucus, which may be derived from the mucous membrane of any part of the urinary tract, including the prostate, pathologically may pass into the urine in amounts in excess of the normal trace.

Lastly, and very uncommonly, lymph may be added to the urine owing to rupture of an obstructed lymphatic into some part of the urinary tract (chyluria). This must necessarily cause proteinuria owing to the addition of lymph proteins (albumin, globulins, fibrin from fibrinogen, and a few red cells).

TESTS FOR INDIVIDUAL PROTEINS

Here only the simple tests and practical points of clinical importance will be considered; the reader is referred to the laboratory textbooks for a fuller account of special tests.

Albumin is the most important of the urinary proteins clinically, and commonly is the main protein excreted. To that extent the term 'albuminuria' is justified, but it may be misleading, as already explained, when used as a synonym for a positive qualitative test for protein. Albumin is soluble in distilled water, and is precipitated from urine by full but not by half saturation with ammonium sulphate.

The *globulins* may be divided into at least two groups: pseudo-globulin, which is, and lipid- or eu-globulin which is not, soluble in distilled water. Both are precipitated from urine by half saturation with ammonium sulphate, or by full saturation with magnesium sulphate, or by addition of anhydrous sodium sulphate to 22 per cent (Howe). The insolubility of lipid- or eu-globulin in distilled water or highly diluted urine is of clinical importance (see Roberts' test below, under 'Mucus').

The *albumin-globulin* ratio has been claimed from time to time to be of clinical importance in differentiating the various types of nephritis. Hiller, McIntosh and Van Slyke showed that when all the urine was collected completely for several days and the average daily ratio of albumin to globulin was determined, the different groups of nephritis did show different ratios. Thus in nephrosis, where there is a big proportionate excess of albumin in the urine, the albumin-globulin ratio is high, generally above 10. In amyloid disease, where there is high output of globulin, the albumin-globulin ratio was low (0.5 to 5.0). In acute nephritis, the albumin-globulin was between 5 and 10, and in chronic it is mainly below 5. The practical point emerged, that the ratios often showed large variations from day to day, and that a single determination on (and still more on one isolated specimen of) a quite untrustworthy in differentiation, and misleading. It may be concluded, therefore,

albumin, over 70,000 by osmotic pressure

is near the borderline, and is peculiarly excreted when its concentration in a certain value.

that the albumin-globulin ratio is not a simple test of practical value.

Hæmoglobin in the great majority of instances is within the red cells, and not free in physical solution in the urine; hæmaturia is much more common than hæmoglobinuria. Much the best and simplest test for hæmaturia is the microscopical examination of the centrifuged deposit for red cells. The best test for hæmoglobinuria is the spectroscopical examination of the urine cleared by centrifuging (red cells pass through most filter papers to some extent) for the two bands in the green of oxyhæmoglobin; a negative finding should be returned only when a layer three or four inches thick has been viewed, as by placing the direct-vision spectroscope above a test-tube full of urine and looking through the long column, an electric bulb being the light source below.

When hæmaturia exists there must also be proteinuria, for even if the red cells be removed by centrifuging, the supernatant fluid is bound to contain albumin and globulin that has gained access to the urine simultaneously during the hæmorrhage.

In hæmoglobinuria the urine is red, or of a smoky tint, or normal in colour, depending upon the extent. Hæmoglobin is itself a protein, so that in hæmoglobinuria the qualitative tests for protein must be positive. Methæmoglobin, also being a protein, gives positive results with the routine qualitative tests.

Fibrinuria is readily recognized from the presence of clots, which, of course, vary in size, depending on the degree of hæmorrhage, so that slight fibrinuria is easily overlooked. The clots are red owing to the entanglement of red cells, except in chyluria, where the cells are usually so few that the clots appear white. The fibrin is easily removed by centrifuging or filtering.

Mucus, in pathological quantity, is much more commonly present in urine than is generally recognized. It behaves in its precipitating reactions very much as the globulins, and has generally been included in the globulin fraction in the differential estimation of proteins. It is precipitated by acetic acid in the cold, as also is lipid- or eu-globulin; but mucus is insoluble in excess, whereas eu-globulin is soluble in even the slightest excess of the acid. It is widely believed in clinical medicine that these two proteins are of little or no importance in the sense that one or both are often found in intermittent proteinuria (see later), and that mucus is often due to cystitis or prostatitis, which are evident from the clinical symptoms and examination. In other words, if the proteinuria is due to a protein precipitated by cold acetic acid, there is no need to worry about kidney damage, so the following test has its clinical application.

Test for proteins precipitated by cold acetic acid.—About 5 c.c. (1-in. column) of urine in a test-tube are mixed with an equal volume of distilled water, and 33 per cent acetic acid is carefully added drop by drop till the maximum opalescence has been obtained. A pause of about a minute should be made after the addition of each drop, because precipitation is slow. Half the contents are then transferred to a second tube, to which a few more drops of the acid are added. In the first tube a precipitate, which is often slight, may be due to mucus or lipid-globulin, or both. In the second tube a precipitate must be due to mucus only, for lipid-globulin re-dissolves in excess acid. If, therefore, the opacity of the two tubes is the same, mucus alone is present; if the opacity of the first is greater than that of the second, both proteins are present; if the first tube is opaque, but the second is clear, lipid-globulin alone is present.

In the writer's experience mucus alone is the commonest finding.

A second test, which is for lipid-globulin, known as Roberts' test, is performed as follows:—

Roberts' test for eu- or lipid-globulin.—A boiling tube (conical receiver or any other convenient vessel) is nearly filled with distilled water, and the urine is added drop by drop. In the presence of eu-globulin a milky haze forms round each drop as it diffuses into

the water. The addition of the drops is continued till the mixed fluid is turbid throughout. Half the contents are then transferred to a second boiling tube. The first tube is left without further treatment for comparison. A single drop only of 33 per cent acetic acid is added to the second tube, when the turbidity clears at once if it be due to eu-globulin.

Proteoses may appear in the urine when absorption of partially digested pus is proceeding somewhere in the body, and during involution of the puerperal uterus. They usually occur in traces only, are often transient, and generally are of little or no clinical significance. They are precipitated below 60°C., re-dissolve on boiling, and reappear on cooling. They may be separated from other proteins by coagulation at 60°C., and filtration.

Bence-Jones' protein behaves in several ways like a proteose; it, too, comes down below 60°C., re-dissolves on boiling (but see below) and reappears on cooling. It, however, is not a proteose, but a full protein, in character mostly closely allied to a globulin, hence it is better to term it Bence-Jones' protein. Its presence in the urine is practically diagnostic of multiple myelomatosis, though it has been described occasionally in other diseases of the marrow. Although uncommon—it is encountered on the average about once a year in a large general hospital—it is of great clinical importance for very often it is the first sign to establish the diagnosis of the patient's illness. It is, therefore, essential to make clear the evidence on which its detection depends.

In the boiling and acetic acid test it may be noted that a precipitate forms relatively early during the application of heat, to re-dissolve on boiling and reappear on cooling. There are several reasons, however, why this behaviour may be modified or missed. The urine should be naturally acid, or made very slightly so by acetic acid; if it is carelessly overacidified the protein may not be precipitated at any temperature. It may be missed, too, by heating very rapidly. Resolution at boiling point is frequently only partial, though it may be made complete or nearly so by correct adjustment of reaction (*see below under heat test*).

As a preliminary, *Bradshaw's HCl ring test* is useful. It is performed by superimposing a few c.c. of the urine on about 5 c.c. of concentrated HCl. Bence-Jones' protein gives a heavy curdy-white precipitate at the junction of the two fluids. The test remains positive after considerable dilution of the urine (one part with 10 or 20 parts of distilled water), unless the concentration of protein is very low. As a rule the proteinuria is marked when first detected but presumably would have been low in an early stage of the disease. If Bradshaw's test is positive the heat test described below should be carried out, to make sure of the protein, for Bradshaw's test is not specific, because any urine containing an abundance of protein will give a positive result, though commonly only a slight haze. Uroselectan in urine gives a false positive reaction. If Bradshaw's test is negative, further investigation is unnecessary, and therein lies its value as a preliminary.

The *two-tube test* is advantageous when there is doubt as to re-resolution at boiling point. About 10 c.c. of urine are warmed to about 60°C., until the tube is just not too hot to grip firmly in the hand. After inversion over the thumb to insure an even temperature and suspension of the precipitated protein, half the contents are transferred to a second tube, which is thoroughly boiled. Immediate comparison with the first tube demonstrates clearly if there is any resolution, and the degree thereof.

The *heat test* is the most important, and should always be done before diagnosing Bence-Jones' proteinuria. The urine is cleared by filtering, repeatedly if necessary, and the reaction noted. If alkaline, it is made very faintly acid by the cautious addition of 33 per cent acetic acid. About 5 c.c. are placed in each of three test tubes. To the first nothing is added; to the second and third, one and two drops of 33 per cent acetic acid respectively, after which they

are placed together with a thermometer in a beaker of water. The beaker is heated slowly, the water being continuously stirred, and the temperatures at which changes occur noted. In the presence of Bence-Jones' protein the urine becomes turbid below 60°C.—often between 40°C. and 50°C. After a further rise of a few degrees (but still below 60°C.) the precipitate flocculates. Ordinary albumin and globulins do not come down till over 60°C., though in their case also the reaction affects the temperature at which they are first precipitated. On boiling each of the three tubes, one at any rate will show complete or almost complete re-solution (remember, however, that proteins other than Bence-Jones' may also be present). On cooling reappearance of the protein will be evident in one at least of the tubes. Thus a composite picture is obtained of the typical behaviour of Bence-Jones' protein. Three different degrees of acidity, as described, suffice in routine work, but clearly a more elaborate series of tubes with smaller steps in reaction are easily prepared. When the conditions are not correct for complete re-solution at boiling point, it will often be observed that the protein forms a peculiar stringy, sticky, coagulum.

So-called peptonuria.—Every now and then when urine is added to Fehling's or Benedict's reagents in the test for 'sugar' it is observed that the mixture in the cold has a deeper blue, or purplish colour, than the original copper reagent. This is often due to the presence of proteins in the urine giving a biuret reaction. But a similar colour change was observed in the absence of proteinuria over fifty years ago (*e.g.*, Ralfe, 1883), and was ascribed to the presence of peptones; when the urine is super-imposed carefully on the reagent a reddish-colour-purple or rose-coloured ring is observed. Godfried has recently studied this phenomenon, and has shown that it is due neither to peptones nor to urobilin (another suggestion), but to a pigment of the urochrome group, or something associated with urochrome. The point is of interest because the practitioner must come across it sooner or later in his routine urinary examinations, but so far as the writer knows it has no clinical significance.

QUANTITATIVE ESTIMATION—ITS CLINICAL IMPORTANCE AND TECHNIQUE

It must be admitted that in routine work the physician can obtain all the guidance he requires from qualitative tests, provided that some notation be adopted to indicate roughly the concentration—large, small, or present in traces. As usual, however, such a notation implies more to the observer than to any one else, and whenever observations are to be published they will convey more to the reader if quantitative determinations have been made. Also, in following progress exact estimations are clearly more useful.

A good review of methods available for estimating protein in urine is given by Peters and Van Slyke, 'Quantitative Clinical Chemistry', Vol. II. *Esbach's method* is well known and widely used clinically, but it is important to realize that it is not strictly quantitative, and little importance should be attached to small daily variations as indicated by this means. Unfortunately, the method is rendered still less trustworthy by quite appreciable errors in the calibration of the tubes on the market. The Esbach's tube is cleaned and dried. Urine is run in exactly to the mark U, and Esbach's picric and citric acid solution to the mark R. The tube is sealed with a rubber bung and inverted several times to mix. It is left undisturbed for twenty-four hours, so that the protein precipitate settles by gravity, and the result noted. The readings give directly the grammes of protein per 1,000 c.c. of urine. Knowing the volume of the twenty-four hours' urine, the day's output of protein is calculated.

The following precautions should be observed: If the urine is alkaline it must be acidified with 33 per cent acetic acid; occasionally the original urine is so alkaline that omission of this precaution results in the subsequent precipitation being incomplete. The specific

gravity of the urine is taken with a urinometer; if the specific gravity exceeds 1010 it is diluted accurately with the necessary one or two volumes of water to bring the specific gravity to or below 1010; the diluted urine is run into the Esbach's tube to the mark U, and next day the observed reading is multiplied by the dilution factor; omission of this precaution results in imperfect sedimentation of the protein precipitate.

In *Aufrecht's method* the protein is again precipitated by a solution of picric and citric acid, but the mixture is centrifuged for two minutes at 5,000 revolutions per minute, or for two and a half minutes at 3,000 r.p.m., or for three minutes at 2,000 to 2,500 r.p.m. It is essential to centrifuge for the prescribed time, otherwise gross errors may be introduced. As in Esbach's method, urine is added to U, and reagent to R, but in the specially designed Aufrecht's centrifuge tube, the readings giving the grammes of protein per 100 c.c. of urine. As before, alkaline urines must first be acidified with acetic acid, but the specific gravity is immaterial. Unfortunately the calibration of the tubes on sale is even worse than that of Esbach's tubes, the chief error being in the calibration of the terminal tapered part, so that two Aufrecht's tubes may give absurdly different results, particularly when the protein is less than 0.1 per cent. With a correctly calibrated tube, results can be obtained in a few minutes if a suitable centrifuge is available.

Centrifuging has also been employed in the *method of Shevsky and Stafford*; the protein is precipitated by a solution of 1.5 gm. of phosphotungstic, and 5 c.c. of concentrated hydrochloric acid in 100 c.c. of 95 per cent alcohol, in a graduated centrifuge tube: 4 c.c. of urine are treated with 2.5 c.c. of reagent; the tube is closed, inverted slowly three times to mix, and allowed to stand for exactly ten minutes; it is then centrifuged for exactly 10 minutes at 1,800 r.p.m. The volume of the precipitate in c.c. is noted, and multiplied by 0.72 to obtain the grammes of protein per 100 c.c. of urine.

THE CLINICAL CONDITIONS IN WHICH PROTEINURIA OCCURS

General discussion.—Proteinuria may be one of many clinical signs or may be the only evidence of any abnormality in a subject otherwise normal. It is, of course, simply a matter of words, or of personal choice whether it be stated that normal urine contains no protein other than a trace of mucus, or whether it be stated that the urine of some healthy individuals contains protein which is of no clinical importance. Some cases of glycosuria provide an exact parallel; thus, glycosuria due to true renal glycosuria is of no moment, but until it has been shown conclusively that the condition is renal glycosuria, the urinary finding may be of serious import. Similarly the medical officer must remember that every case of proteinuria needs investigation before he can be satisfied that it is immaterial. The subject is discussed further under 'intermittent proteinuria'.

When there are clinical signs or symptoms in addition to proteinuria, the significance of the proteinuria must be determined in the light of such findings, and upon the conclusions drawn from the whole of the evidence will be inferred what is the probable cause of the proteinuria, and accordingly its course may be predicted. There is no foundation for a separate discussion of the prognosis or treatment of proteinuria or of any other clinical sign. It is the underlying disease or condition responsible for the clinical sign which may require prognosis and treatment.

The compilation of the huge list of all possible diseases and conditions in which proteinuria may occur would clearly be of little or no value, but it is necessary to have some sort of order in thinking of the possible causes and clinical condition when the qualitative tests for protein in the urine have been found to be positive. The writer's practice is to think in anatomical sequence from the exterior inwards, from possible contamination to lesions of the genito-urinary tract in ascending order, and, finally, to the blood and other sources from which the blood may carry protein

to the kidneys. It is obvious that the responsible lesions may be situated in more than one anatomical site, as when both urethra and prostate are involved in gonorrhoea or when both bladder and kidneys are diseased in tuberculosis, and so on, but the anatomical sequence is convenient. The subject will be dealt with in that order now, a few practical points being inserted here and there under the different headings.

Contamination as the cause of proteinuria has been considered in the early part of this article.

Diseases of the external genitalia or of the urethra.—The venereal diseases, non-specific urethritis, trauma of the urethra, externally or by calculus or gravel, and so on: the heading is sufficient.

Diseases of the bladder or prostate.—Cystitis, tuberculosis, vesical calculi and growths, etc. Enlargement of the prostate and its cause. As mentioned above, an excess of mucus in the urine is most commonly due to lesions in this region, and the microscopical examination of the urinary deposit is indispensable. In chyluria, the obstructed lymphatic most commonly ruptures into the bladder.

Diseases of an ureter or ureters are uncommon causes of proteinuria, the most frequent among them being stone.

Diseases of a kidney or kidneys are generally the first to be considered, and sometimes, unfortunately, are thought of as the only cause of proteinuria; there are many causes of 'albuminuria' in addition to nephritis. The renal lesions may be classified under two headings: (a) kidney diseases proper; (b) secondary disorders of kidneys.

Kidney diseases proper.—Trauma; nephritis; tuberculosis; stone; tumour, and so on. Reference to casts and the proportion of albumin to globulin has already been made. The concentration of protein in advanced chronic nephritis may be very small and its detection important; in nephrosis, as a rule, it is high.

Secondary disorders of kidneys.—Under this heading are included vasomotor and circulatory disturbances in the kidneys themselves. Thus 'intermittent or benign proteinuria' may be classified here, but is considered in a separate section below, as also is 'proteinuria in pregnancy', many examples of which are due to congestion of the kidneys from pressure by the gravid uterus. Congestion due to a failing heart is in the same category, likewise the circulatory effects in diabetic coma. Proteinuria due to surgical shock, or to cold baths in certain subjects, comes here too. Febrile proteinuria is more difficult to place accurately. In fevers there is undoubtedly a complicating nephritis in a proportion of cases, and this would of course be classed as 'kidney disease proper'. But in much larger proportion of cases the proteinuria is transient and unaccompanied by any clinical signs of renal involvement; some at least of these proteinurias may be regarded as due to renal congestion. In a small proportion of cases, and after scarlet fever in particular, it may be difficult to assess the significance of the proteinuria, which in some instances persists for years; possibly some of these were present before the fever (see also under 'intermittent proteinuria'). Though febrile proteinuria is often classified, together with albuminuria, due to poisoning by chemicals, under the heading of 'toxic', it seems more logical to separate the chemical poisons and to regard their action as definitely productive of renal damage. Experimentally there is clear-cut evidence of this, and clinically the testing of the urine for protein before and after administration is a practical and useful means of detecting damage to the kidneys by such drugs as the organic arsenicals, mercury, antimony, etc., and such proteinuria is an indication for cessation of treatment. In industrial or in deliberate poisoning (arsenic, lead, mercury, etc.), the proteinuria may be significant, as when accompanied by clinical signs of kidney damage, or of uncertain import if there are no such signs, and the urine was not known to be free from protein before exposure to the risk.

Intermittent proteinuria is of the greatest practical importance, and produces problems frequently and particularly in insurance work. It is described under a

large number of synonyms, such as orthostatic, lordotic, cyclic, benign, physiological, functional, albuminuria of adolescence, and so on. In the first place contamination of the urine must be excluded (*see* previous section), for that is often intermittent. Secondly, the subjects of this condition often show signs of cardiac or vasomotor instability, and many are 'weedy', pale, spotty, or overgrown. This type of proteinuria occurs most often at adolescence, but is not limited to that period. Theoretically there might be a slight organic lesion somewhere in the urinary tract which was drained at intervals, and a few patients with intermittent proteinuria have been observed subsequently to suffer from tuberculosis or stone. In a large number, but not all, posture influences the proteinuria. There may be no proteinuria whilst in the horizontal position, followed by varying grades of proteinuria on adopting the exact attitude. It has been suggested that in these individuals there is an imperfect vasomotor control, so that the kidneys become temporarily congested in the upright position. The proteinuria is frequently most marked during about two hours after rising, later becoming less or disappearing, and still later in the day reappearing or intensifying. Lordosis has been noted in some, and has been put forward as a cause of renal congestion, but intermittent proteinuria occurs without lordosis, and *vice versa*. If posture markedly affects its degree, it is a point in favour of the proteinuria being of no importance.

It is generally accepted that ingested proteins are invariably digested and absorbed only as amino-acids, and there is no unequivocal evidence that protein by the mouth, however large the amount, has any influence on the excretion of protein in the urine of man.

Strenuous muscular activity is well recognized as causing or increasing proteinuria intermittently, as in soldiers, athletes, members of rowing crews, etc., but does so only in the minority. Renal congestion may be the explanation, but clearly it is necessary that each case be carefully examined to exclude other and serious causes.

This brings us to the practical point of what evidence should be secured before labelling proteinuria 'benign'. Having made a thorough clinical examination, and having excluded contamination, the fact that the proteinuria is intermittent itself is a strong point in favour of its insignificance, though it has been found that proteinuria may become intermittent in the last stage of a nephritis which is clearing up, particularly after scarlet fever. If it is clearly influenced by posture, that again makes an organic lesion unlikely. To show the effect of posture, the subject is instructed to empty his bladder completely on retiring, and again one or two hours after lying in bed, and these samples are discarded. The specimens passed just before rising, and about two hours later after normal activity in the erect position, are tested. In typical cases the first urine does not, whereas the second does, contain protein, and often in high concentration. Samples later in the day, as previously mentioned, vary in protein content, but quite often the 'albuminuria' disappears after some four to six hours, to reappear later in the evening. An examination of the centrifuged deposit should always be made; all samples containing protein should be so inspected; the method has been discussed in a previous section. An occasional leucocyte, epithelial cell, hyaline cast or cylindroid may be disregarded, but red cells and all other casts should raise the suspicion of the presence of an organic lesion, until repeated and prolonged observations have justified the conclusion that they are immaterial. If it can be shown that the protein is mucus it is not likely to be of importance, but otherwise a study of the nature of the proteins is seldom of practical assistance. Renal efficiency tests are of value to exclude gross lesions, but normal findings with these tests by no means indicate that the kidneys are healthy. One or more should be carried out as a safeguard, but the decision as to whether the proteinuria is benign or indicates a mild organic lesion depends on the other evidence considered above.

Proteinuria in pregnancy is very common, and its significance in a particular case often of moment in practice. It has long been recognized that in the great majority of pregnant proteinurics the positive urinary test is of no importance, and is ascribed to congestion of the kidneys due to the pressure of the gravid uterus on the renal vessels. With the modern practice of repeated urinary examinations throughout pregnancy, it has become much easier to assess the significance of the proteinuria: any sudden increase just before term, for instance, and any change in the urinary deposit being revealed.

For a satisfactory study, especially in the last month or so, it is essential to avoid contamination by vaginal discharge by careful cleansing before micturition; catheterization may be required, but is usually unnecessary for purely chemical and cytological examinations and there is no point in running any unnecessary risk of infection.

The chief aims of the tests for protein are the detection of nephritis or other organic renal lesion in a woman who has become pregnant, and to obtain warning of the onset of pregnancy toxæmia, and especially of eclampsia.

Proteinuria without lesions of the urinary tract.—Under this heading are included the excretion of foreign proteins introduced by injection, proteosuria, Bence-Jones' proteinuria, and so-called peptonuria. All have been dealt with in previous sections.

The Use and Abuse of Manipulative Surgery

By A. S. BLUNDELL BANKART, F.R.C.S.

(From the *British Medical Journal*, Vol. II,
29th August, 1936, p. 416)

A FEW weeks ago an elderly lady told me that according to her information manipulative surgery was 'brute force and bloody ignorance'. I told her that this was the best definition I had heard. Perhaps it is significant that in spite of this she entrusted herself to me for manipulation of her spine, showing that some of the more intelligent of the public are able to distinguish between manipulative surgery and the proper use of manipulation in surgery.

I have no wish to quibble about the meaning of a word or a phrase. I have used the term 'manipulative surgery' many times, and once I so far forgot myself as to write a little book with that title. But it is a term to which I have the strongest objection, because it implies or suggests that the use of manipulation is something different and apart from ordinary surgical procedure, and that it is a peculiar method or system of treatment which is no particular concern of the ordinary surgeon or, for that matter, of any surgeon. This is not true; but we may as well admit that not so long ago it was true, or almost true. Manipulation was practised empirically by bone-setters in this country for centuries before its possibilities were realized by the medical profession. In fact, it is little more than twenty years since the conspicuous success of one bone-setter in particular forced the medical profession to take manipulative surgery seriously. Personally, I have never been afraid or ashamed to admit that my own enlightenment came from Herbert Barker—not directly, for I never saw him at work, but from the simple fact that he cured outright a patient of mine whom I had treated unsuccessfully by orthodox methods over a long period.

Many years ago I received a letter from an intelligent middle-aged woman, who wrote as follows:

'Dear Mr. Bankart,

'You may remember that two years ago I consulted you for pain in my feet due to flat-foot. For two years I had your treatment and I did everything that you told me to do. I wore the special boots that you had made for me, and the wedges, pads and supports. I had the massage and I did the exercises which you prescribed for me. But I got no better, and I began

to fear that I should be crippled for life. Then some friends of mine persuaded me to consult Mr. Barker the bone-setter. He, with his wonderful hands, put the bones of my feet back into place, and now, I am thankful to say, I am cured. I have no pain in my feet, I can walk seven miles with ease and comfort, and I feel that a new lease of life has been granted to me.

No doubt your first comment on this case will be that I must have treated this patient very badly, and I entirely agree. But at least I will say that I treated her conscientiously and according to the accepted principles of all the leading orthopaedic surgeons of the day. Yet I had failed, and my patient had gone off to a bone-setter, who had cured her. Perhaps your next comment will be that the universal diagnosis of 'a small bone out of place' is so manifestly false that you are sceptical of cures which are alleged to have been brought about by 'putting small bones back into place'. But you must understand that 'a small bone out of place' is not a diagnosis, but a pretext. The bone-setter must find a reason or an excuse for manipulating a joint, and I must confess that I find it difficult not to take off my hat to the man who first thought of 'a small bone out of place'. Hard things have been said about the medical profession for its tardy recognition of manipulative surgery. But if bone-setters had wished to keep their work to themselves they could hardly have done better than choose a name which is misleading—for whatever else they do they do not set bones—and an explanation of their results which is demonstrably untrue.

FOOT STRAIN

In the case of my patient I had no doubt that she was telling the truth, and that, whatever the explanation, she had been cured of her complaint. I asked myself first: What did he do to her, or, for that matter, what could any man do to a foot with his hands alone? The answer was that he could do nothing except move it. How, then, could one man's movement or manipulation differ from that of another, for we had often manipulated feet, but without such dramatic results? The answer was that he could only move it with more force or in a different direction, or both.

So here was the explanation, and surely it is simple enough. It is a story that I have told so many times that I have not the face to weary you with it again in detail. It is enough to repeat that people do not suffer from flat-foot, but from inability to flatten their feet. The great majority of civilized people have acquired some restriction of the natural mobility of their feet, so that they cannot flatten without meeting with the resistance of the soft parts. When the flattening foot meets with this resistance it is strained, and the condition is painful. On the other hand, the completely flat foot is painless. The medical profession and the public have been obsessed with the idea of supporting the arch of the foot. In theory this is ridiculous, for the foot was meant to be an active, supple member, and not a rigid thing like a block of wood; and in practice it has proved a miserable failure. The bone-setter, on the other hand, smashed down the arch of the foot, or, to put it less crudely, he restored its mobility, so that it could flatten without resistance and therefore without pain, and he cured his patients. Most appropriately my experience has led me to mention first the commonest use of manipulation in surgery. For foot strain (not flat-foot, if you please) is one of the commonest ailments of the human body. It may be postural or traumatic in origin. It can be cured by manipulation and in no other way. See to it that you cure it, or others will cure it for you, as they have done in the past.

Now listen to a very different story. Some years ago a doctor brought his son to me with an obviously tuberculous elbow. He had taken him first to a bone-setter (not Barker), who had violently manipulated the joint, and it had flared. The doctor felt and looked a fool; but there it was. No doubt your first comment on this

case will be that the bone-setter ought never to have manipulated this joint, and he knows that as well as you do, now. But how was he to know that this was a tuberculous joint, for he had had no medical or surgical training? Then, you will say, he ought never to manipulate any joint, or, in other words, he ought not to exist. Perhaps you are right; but what about my lady with the supposed flat-foot, and the countless other cases that have been cured by bone-setters after having failed to get relief elsewhere? Do not think that I am talking only of the past. I still hear of orthopaedic surgeons of repute who treat so-called flat-foot with arch supports, who do not recognize sacro-iliac strain, the commonest cause of pain in the back, and who profess to be familiar with manipulative surgery but who seldom practise it. You cannot have it both ways. It is no use saying that the bone-setter ought not to practise because he is not medically qualified unless you, who are medically qualified, are prepared to undertake not merely an occasional manipulation or two, but the whole of the manipulative work that has hitherto been performed by bone-setters. How many of you who are attached to large hospitals have any organized arrangements for dealing with the large number of cases which require manipulation in ordinary orthopaedic practice?

SPINAL CONDITIONS REQUIRING MANIPULATION

After the foot, the joints of the pelvis and spine are those which most often call for manipulation in the ordinary course of treatment. I will not inflict the Americanism 'low back pain' upon you. Low back pain is about as intelligent a diagnosis as belly-ache or pain in the chest.

Sacro-iliac strain is the commonest cause of persistent pain in the lower part of the back. It is a definite clinical entity, characterized by pain in the sacro-iliac joint, tenderness on pressure over the posterior superior spine of the ilium, a sense of insecurity or weakness, and, in most cases, a normal x-ray picture. Pain may be referred to the outer side or front of the thigh, but never down the sciatic nerve in an uncomplicated case of sacro-iliac strain. Sometimes there is chronic arthritis of this joint associated with a similar condition of the joints of the lumbar spine. Occasionally there is tuberculous disease of the sacro-iliac joint, but this is practically never seen before there is visible evidence of bone destruction in the x-ray picture. So that with the simple precaution of a routine x-ray examination one can diagnose and treat a case of sacro-iliac strain without hesitation. We believe that sacro-iliac strain is a chronic strain or sprain with periarticular adhesions such as may occur in any other joint. Often there is a definite history of injury, and the strain is common after childbirth, but sometimes it is of gradual onset and due to faulty posture. Over 90 per cent of the cases can be cured by manipulation under an anaesthetic followed by massage and exercises. Those which do not respond to manipulation can be cured outright by arthrodesis of the sacro-iliac joint.

Chronic lumbar back strain is perhaps the next most common cause of persistent pain in the back. It begins acutely with a sharp stabbing pain during some effort or awkward movement. It is due to rupture of some of the deeper fibres of the erector spinae muscle on one or other side. When the condition becomes chronic there is a point of local tenderness over the erector spinae, spasm of the muscle resulting in limitation of movement, and often a considerable degree of neurosis. Practically all these cases can be cured by manipulation, unless there is an impending claim for compensation or a long-standing traumatic neurasthenia.

Spinal arthritis—that is, osteo-arthritis of the lumbosacral and intervertebral joints of the lumbar spine, with or without sciatica—is the third condition of the spine which in suitable cases may be treated by manipulation. We do not pretend to perform a miracle on the permanent osseous changes of advanced chronic arthritis here or in any other part of the body. But do believe that a great deal of the pain of which these

patients complain is due to periarticular fibrosis rather than to actual changes in the joints, and that, if the spine can be made supple again, much of the pain will disappear. Forceful manipulation followed by vigorous massage and exercises is successful in about 50 per cent of these cases. It is irrelevant to add here that, when all other means fail, excision of the corresponding intervertebral joints is an almost certain cure for intractable sciatica.

THE KNEE-JOINT

Many people, I think, would say that I should have placed the knee-joint first, or at least second, in the list of those that may require manipulation. But the knee-joint, perhaps, is the one joint which is manipulated more often than it ought to be. Nowhere is the difference between manipulative surgery and the proper use of manipulation in surgery more evident. The practitioner of manipulative surgery alone must manipulate at all costs or confess himself beaten, for he has no alternative methods of treatment. The properly equipped orthopaedic surgeon, on the other hand, has at his disposal all the resources of medicine and surgery, and not the least of these is the use of manipulation in suitable cases.

For many years bone-setters have claimed that they can cure cases of displaced semilunar cartilages by manipulation. It is not true; but here again we have learnt something from the bone-setter. Chronic knee-sprain can be cured by manipulation. In such cases the injury has stopped short of that gross injury which results in a torn cartilage, and has produced instead a sprain of the peripheral attachment of the cartilage. When this condition becomes chronic the patient complains of frequent stabbing pain on the inner side of the knee, occasional attacks of synovitis, and weakness of the joint. He may say that the knee gives way, or slips, or 'goes out', but there is never any mechanical obstruction to movement. These cases are common enough; the symptoms, of course, are due to fibrosis or 'adhesions' at the periphery of the cartilage, and they can be cured by manipulation; and inasmuch as they are usually diagnosed as 'slipped cartilage' by bone-setters and the public, they are largely responsible for the popular belief that displaced semilunar cartilages also can be cured by manipulation.

SEMILUNAR CARTILAGE DISPLACEMENT

We now know that a displaced semilunar cartilage is always a torn cartilage, and that when once a considerable part of it is detached and loose the only place it can go to and not give rise to immediate trouble is the centre of the joint. The freeing of a 'locked knee' by manipulation and the further displacement of the detached cartilage into the intercondylar notch may be followed in some cases by a considerable period of immunity. But it is my belief that such a cartilage always gives rise to trouble sooner or later, and that is not what I call a cure.

In the aggregate the surgeons here must have operated upon thousands of semilunar cartilages. In my experience a large proportion of the patients give a history of having put the knee out previously, it may be years before; 'but', they tell me confidently, 'that was put right by a bone-setter'. At operation one finds the typical tear of the cartilage which could not possibly have been 'cured' by any manipulation, although, as I have already said, the manipulation may have been followed by considerable period of immunity from

... that is not the whole story. We see chronic synovitis of the knee passing in patients approaching middle age, who admit that many years ago they 'put a cartilage out, but that was put right by a bone-setter'. These are neglected cartilage injuries, or shall I say, cases in which manipulation has been misapplied. I feel strongly that a semilunar cartilage once torn and displaced in the knee-joint of a reasonably young and healthy individual should be removed forthwith, for if it is left it will ultimately destroy the joint.

You will hardly expect or wish me to recount all the uses and abuses of manipulation in and out of surgery. I think I have said enough to show that manipulative surgery is and must be an integral part of orthopaedic surgery. That it has not always been so I am the first to admit; but we are concerned with the present and the future, and not with the past. Within the last twenty years, for the first time in history, manipulative surgery has been placed upon a sound scientific basis, and we know far more about it now than any bone-setter has ever known. The most striking thing about it is its extreme simplicity. There is no complicated pathology attached to manipulative surgery. The greater part of it is concerned with the simple inflammatory reaction of living tissues to injury—the first thing that we learn when we begin to study medicine—which, in various parts of the body, leads to fibrosis or adhesions in ligaments or muscles, limiting movements of joints, and causing pain when movements are attempted. Manipulation consists merely in moving a joint forcibly through its full range of movement, I would emphasize the point that manipulation in general requires the use of great force, and that the art of manipulation consists of applying great force effectively and safely. Tweaking joints is no part of manipulative surgery.

Frankly, I do not think that the bone-setter abused manipulation so much as some people would like to make out. The genuine British bone-setter, now almost a figure of the past, was for the most part an honest fellow, who did work which nobody else would do, and believed in his work and was largely justified in his belief by the results he obtained. Being entirely without medical or surgical training he could not make an exact diagnosis, and it is not surprising that occasionally he met with disaster. But that, I am charitable enough to believe, was his misfortune rather than his fault.

OSTEOPATHY AND CHIROPRACTIC

I should like to stop now; but no account of the abuse of manipulative surgery would be complete without some mention of those American stunts which go by the names of osteopathy and chiropractic. It is little more than sixty years since an obscure American physician called Still announced that it had been revealed to him by God that practically all diseases are due to slight displacements of the spine, which produce pressure on the blood vessels in the intervertebral foramina, and so cause disease in various parts of the body. He devised a series of manipulations which had for their avowed object of replacement or 'adjustment' of these so-called spinal lesions; by these manipulations, it was claimed, the pressure on the blood vessels was relieved, and the diseases resulting therefrom were cured. He called this treatment osteopathy, and osteopathy it is.

Do not let anyone deceive you by explaining that this is ancient history, and that the 'modern osteopath'—whatever that may mean—is a more enlightened fellow who has become, in fact, a 'manipulative surgeon'. This is not true. It is true that the osteopath has shifted his ground again and again as one after another of his claims has been shown to be absolutely devoid of any scientific foundation. Pressure on the blood vessels in the intervertebral foramina gave way to 'congestion', and then to 'interference with the autonomic nervous system', and latterly an attempt has been made to identify the imaginary 'osteopathic lesion' with the chronic back strain which we know so well. In treatment, too, the osteopath has shifted or extended his ground in that he may employ local treatment in addition to, but not as a substitute for, the spinal 'adjustments' which are the essential basis of osteopathic treatment. I need hardly remind you of the impudent attempt which was made a year ago to establish by law a virtual monopoly of manipulative surgery for osteopaths in this country. Osteopathy has nothing whatever to do with manipulative surgery. It is an American 'stunt' based on the unsupported

assertion that practically all diseases are due to imaginary displacements of the spine. It has been investigated up to the hilt, and it has been found wanting.

About twenty years after Still, another obscure American called Palmer, without any medical qualifications, announced that he had made the 'discovery' that 95 per cent of all diseases are due, not to pressure on the blood vessels at all, but to pressure on the nerves of the intervertebral foramina, brought about by the same imaginary displacements or 'lesions' of the spine. He employed manipulations similar to those of Still, but he called his system of treatment chiropractic. This rival venture proved even more successful than its prototype, judging from the fact that there are far more chiropractors than osteopaths in the United States and Canada. There is little to choose between them, but it is the osteopaths particularly, with their more pretentious claims, who have tried to establish themselves in this country. It is up to orthopaedic surgeons to see that these confidence tricks are exposed, and to ensure that the proper use of manipulation in surgery is taught and practised in all our teaching hospitals.

Treatment of Chronic Rheumatism

By H. LETHEBY TIDY, M.D., F.R.C.P.

(From the *British Medical Journal*, Vol. II, 29th August, 1936, p. 418)

I SHALL assume that there are three clinical groups included in the term 'chronic rheumatism'—namely, rheumatoid arthritis, osteo-arthritis, and fibrositis. I shall also assume that the term does not include acute rheumatic fever, or arthritis associated with specific infections such as gonorrhœa, or associated with gout, organic nervous diseases, or with certain other obvious factors such as hæmophilia. I shall not further define the subject of our discussion, and shall proceed to review the various methods of treatment which are available.

PRESENCE OF A SEPTIC FOCUS

All cases should be carefully examined for a septic focus, and when such is found it should receive the appropriate treatment. The opinion of the dental surgeon should be followed, but indiscriminate extraction of teeth, which is usually contrary to his advice, should be discouraged. These steps constitute the routine procedure in the treatment of most chronic conditions. But I do not agree with those who consider there is sufficient evidence for the view that bacterial action is the invariable cause of chronic rheumatism, and, in the absence of anything more definite, will accept as the cause some organism which is isolated from the stools and possesses slightly irregular sugar reactions.

Vaccines.—Those who hold that vaccine therapy is the correct treatment for chronic sepsis are justified in employing it when a definite focus is identified. But there is no justification for the routine use of vaccines in chronic rheumatism. We know that sepsis will disturb a diabetic regime, but it is not suggested that vaccines are a treatment for diabetes. No evidence that is satisfactory, or even nearly satisfactory, has been produced in support of the use of vaccines in chronic rheumatism within the definition of our discussion. It is particularly illogical to employ in chronic rheumatism irregular methods of vaccine therapy which have no support in general use.

DRUGS AND DIET

Analgesics such as aspirin may relieve aching, especially in fibrositis, though failure is frequent. Many an osteo-arthritic has faith in iodine and in 'Chelsea pensioner' for easing pain. Gold is the only drug for which a specific effect can be claimed, and its use is limited to rheumatoid arthritis. Its introduction is due

to the French view that rheumatoid arthritis is tuberculous in origin, a theory which is not accepted in this country.

I have seen several cases in which there was undoubted improvement during a course of gold injections. But results are difficult to evaluate in a condition which is liable to exacerbations and remissions, and further study is necessary before its value can be accepted as established. There is a distinct risk of producing a serious form of dermatitis by its use. During a course of gold injections the local care of the joints must not be omitted.

Chronic rheumatism may develop in association with or at an age when hypothyroidism is common and the general condition will benefit from the administration of thyroid, but there is no reason to ascribe any specific action to thyroid. With regard to hyperthyroidism, Dr. Gardiner-Hill has examined extensive material and finds no evidence that it is associated with any type of chronic rheumatism.

Local treatment with drugs is almost confined to the analgesic action of methyl salicylate in rheumatoid arthritis, to Scott's dressing in osteo-arthritis, and to other similar measures. In certain types of fibrositis pain may be relieved by injections of saline or of such substances as quinine urea hydrochloride.

Diet.—There are few principles of any value, in spite of the firm belief of the public in a diet chart. The diet should be well-balanced and contain a sufficiency of vitamin. Patients with rheumatoid arthritis are often thin, and fat appears to be indicated, but increase in weight is more often associated with a remission of symptoms than attributable to the diet. In obese osteo-arthritic subjects weight should be reduced by systematic dieting. Sufferers from fibrositis know that an attack will be precipitated by special articles of diet, such as malt liquors.

LOCAL AND PHYSICAL TREATMENT

In rheumatoid arthritis absolute rest in bed is essential while there is pyrexia and the joints present the appearance of acute inflammation. Vincent Coates' phrase may be recalled: 'The treatment of every case is orthopaedic from the start'. The object is to prevent or control the development of deformities and adhesions. The joints must be placed in splints and in the positions opposed to those deformities which are known to develop. The splint must be taken away and each joint moved daily. The object of this is to prevent adhesions and not for the benefit of the muscles. A single movement in each direction is thus sufficient, and the repetition which is often encouraged is inadvisable. It is essential that the joint should not bear weight during the movement, nor indeed should an inflamed joint bear weight at any time. Active movement is better than passive, especially if contractures have already developed, since it is less apt to cause injury to the joint in the early stages of treatment.

Heat is indicated in all forms of chronic rheumatism. It tends to relieve pain and stiffness of the muscles, to improve the capillary circulation, and to promote the resolution of inflammation and effusions. It may be applied locally or by electrical and balneological methods. For rheumatoid arthritis radiant heat lamps are the simplest method.

Massage is a valuable part of treatment in most forms of chronic rheumatism. It is especially helpful in fibrositis, as it assists in dispelling nodules and adhesions in muscles and deep tissues before these become organized. It also improves circulation and muscular tone, and thus is of value when muscles are tending to waste and atrophy, but it cannot affect adhesions involving joint tissues.

MOVEMENTS

Movements exercise the muscles and militate against adhesions and diminished mobility of joints. They are an integral part of the treatment of practically all types of chronic rheumatism at some stage. It should be

emphasized that no joint should be moved while it is bearing weight, or at least that the weight should be reduced to a minimum. In osteo-arthritis movements are best employed in conjunction with balneotherapy. If pain comes on during movements or exercise it is evident that the movements have been excessive, and the same is probably true of pain developing at night. But pain on movement after a joint has been at rest is no contra-indication to the use of movement in treatment.

Massage, movements, and all methods of physical treatment and balneotherapy should be under the direction and sufficient supervision of a medical man. There can be little doubt that the degree of massage, for example, is at times excessive. Unfortunately few medical men have the necessary knowledge and training, a defect which, it is hoped, will be reminded in the next medical generation.

ELECTRICAL TREATMENT AND RADIATION

There are numerous methods of administering electrical treatment and radiation. Many are convenient for applying heat, with the undeniable result of relieving pain, though unfortunately, this is often only temporary: such is the effect of radiant heat or electric light in rheumatoid arthritis or infra-red light in osteo-arthritis. Diathermy heats the deep tissues, but it may be doubted if it has any advantage over other methods except in rapidity and for osteo-arthritis of the hip. It is not devoid of undesirable after-effects, and its value has been over-estimated; indeed, exaggerated claims have been made for the results of many methods. I can find no satisfactory evidence of any benefit from ionization or deep x-ray therapy.

The faradic current is of great value in the intramuscular forms of fibrositis, the muscular contractions produced dispersing and removing nodules and adhesions. It also aids the control of muscular wasting in all forms of chronic rheumatism.

BALNEOTHERAPY, MINERAL WATERS AND SPA TREATMENT

The value of treatment at spas has been recognized almost from the beginning of history. For many hundreds of years a spa depended on the reputation of its 'cures', and no attempt was made to explain how the waters or medium acted.

About eighty years ago lengthy analyses of spa waters began to appear, patients being left to draw their own conclusions. Later, the results of much so-called research were published, few of them fulfilling the canons of scientific evidence and research. The aim appears to be to prove that the good results of a certain spa are due to the presence of some substance or quality in its waters which is absent from the waters of other spas. The unprejudiced observer can feel little doubt that many spas with widely different waters and surroundings produce approximately similar results. Unless something more definite, or, alternatively something common to many spas, can be produced with scientific support, the profession and public may decide that the various claims cancel out, and that the maximum benefit from treatment can be obtained without visiting a spa.

EXTERNAL USES OF SPA WATERS

There is no evidence that there is any appreciable absorption by the skin of the ingredients of any medium used for 'baths', either water, peat, or other varieties of mud. Those who claim that the result of any balneological or spa treatment is due to such absorption have the burden of proof laid on them.

Beneficial results, therefore, depend on physical qualities and effects, such as temperature, specific gravity, consistency, and percussion. The action may be, first, mechanical. The weight on the joints is reduced and movements of weakened muscles are thus aided. This is a very important action. Secondly, it may be thermal. A warm medium will raise the temperature of the skin and increase the rate of peripheral circulation. Together with the mechanical action, this may greatly relieve pain and at the same time assist

movement. Peat and mud baths combine mechanical and thermal effects to a greater extent than water, and the deep mud pools are of special value in osteo-arthritis and fibrositis. A cold medium is stimulating, as everyone appreciates from sea-bathing, but it has little part in the treatment of chronic rheumatism.

Thirdly, there is the percussion effect. This may combine the good results of heat, massage, and movements, as is shown in whirlpool baths. The same result may be achieved by the massage douche, performed with various types of needle baths and jet douches. The physical action may have some physiological effects on the kidney and cardiovascular system, but there is little evidence that balneological treatment directed against chronic rheumatism achieves appreciable results of this kind, and exaggerated claims have often been made in the past.

The effects here described are those of balneotherapy, and the treatment can be made available anywhere. In the past such substitutes for spas have too often been incomplete and on the unsatisfactory basis, by reason of the large financial outlay involved, but there is no reason why they should continue to be so.

All spa and most balneological treatment is influenced by the length of time devoted to it. Patients desire the maximum effect in the minimum of time and look for intensive treatment. They would possibly do better if they arrived at the maximum effect in the maximum time, but duration is largely controlled by the purse and by opportunity, and partly by the mental outlook of the patient. Experience has led to general agreement that a course of treatment should not exceed a few weeks, and that longer periods cause debility. But the course can be repeated after an interval.

The question of the value of the internal use of spa and medicinal waters is a thorny one. Reports of so-called researches, often widely disseminated through the post, have in the past been little more than advertising propaganda. So far as chronic rheumatism is concerned, there is at present no satisfactory evidence of any special beneficial effect, even in the presence of radio-activity. Of course the general health of many individuals will benefit from a period under a regulated regime.

Indications and contra-indications.—Balneotherapy and spa treatment for chronic rheumatism are contra-indicated in advanced diseases of the heart, lungs, and kidneys, and in all conditions of severe debility. In rheumatoid arthritis simple hot-water baths aid movements at joints help to relieve pain, but other balneological treatment in general is contra-indicated. Balneotherapy is of special value in osteo-arthritis and in the intramuscular forms of fibrositis.

The Importance and Advantages of Prescription Writing in Medical Practice

By E. FULLERTON COOK, Ph.M.

(Abstracted from the *Journal of the American Medical Association*, Vol. 107, 19th September, 1936, p. 965)

A PRESCRIPTION SHOULD BE DISTINCTIVE

WHILE the ideal of medical practice is to use a single therapeutic agent of known physiologic value, it is often advisable to employ a suitable vehicle and to vary this so that the medicine may be distinctive. This applies to all forms of medication, such as liquids, powders, capsules and ointments. A pleasant flavour, an odour that suggests something other than a medicine, an added colour are all legitimate enhancements to a prescription and make the medicine less likely to be duplicated. Those who deal with the sick are conscious of the influence of suggestion; a belief in the physician and his treatment is a powerful influence for relief and cure.

ADVANTAGE OF CO-OPERATION BETWEEN THE PHYSICIAN AND THE PHARMACIST

If the physician in practice is unfamiliar with suitable flavours, colours and vehicles, he has a tendency to order ready-made preparations rather than to write, a

prescription containing the ingredients desired. Other factors that sometimes lead to 'ordering' in place of 'prescribing' are complexity of the pharmaceutical problem involved or lack of information as to dosage, solubility, chemical reactions and other factors.

In these strictly pharmaceutical problems the skilled pharmacist can often help the physician. He can also supply information concerning manufactured medicines, and co-operation with a competent pharmacist will frequently prove beneficial to the patient.

The intensive training of the physician and the elaborate machinery for preparing, standardizing, checking and distributing medicinal substances are all animated by the needs of a patient. To meet this situation there comes the physician, skilled in diagnosis, familiar with the most effective methods of treatment and having at his command a knowledge of the action of medicinal substances and knowing when they are indicated. But his medical skill frequently cannot function effectively if there are not available the carefully prepared and standardized ingredients for his prescriptions, already produced by expert pharmacists, chemists, bacteriologists or biologists, and made available through the pharmacist in the hospital or the community.

IMPORTANCE OF THE SCIENTIFICALLY CONTROLLED MANUFACTURING LABORATORY

In the background there must stand to-day the manufacturing laboratories, with efficient equipment and rigid control over every step of manufacture. These must produce standard inorganic and organic chemicals, such as ether, potassium iodide and sodium salicylate, complex synthetics such as arsphenamine, biologicals such as diphtheria antitoxin and rabies vaccine, biologically standardized pharmaceuticals, including preparations of digitalis and pituitary, sterile products for parenteral administration and the hundreds of other needed chemicals and pharmaceuticals.

The trained pharmacist serves as a liaison officer in the hospital, the medical centre and the community. His specialized knowledge concerning the available medicines should be of inestimable value to the physician in both the selection of medicines and their combination.

THE PRESCRIPTION FOR THE INDIVIDUAL

The prescription written for the individual patient is an important link in a perfected service. An original prescription shows evidence of professional skill and is not a product with which the patient is already familiar through its display in the type of medicine store where no professional knowledge is present and where such standards must necessarily be low.

The latter situation is worthy of serious consideration, for the patient is likely to question the justification for a doctor's fee when it results in what may appear to be a 'patent medicine' type of treatment. Physicians are also realizing that the patient is almost certain to recount his or her experience when talking to friends, perhaps to the discredit of the doctor. Even the naming of such trademarked medicines under these circumstances often leads those who hear the discussion to buy the same medicine to relieve self-diagnosed symptoms. The alarming increase in the use of hypnotics, without medical advice, illustrates this danger.

The use of abbreviated official titles written into a prescription and with a 'non rep.' order controls the situation, while the suggestion to 'buy it at the drug store' opens wide the door to self-medication.

OFFICIAL MEDICINES NOW LARGELY USED

In proposing the use of official medicines on prescriptions it is not being suggested to physicians that they seriously modify the present-day custom of most doctors. In a scientifically conducted survey of the actual ingredients used by physicians in their prescriptions during 1931-1932, a study covering typical communities throughout the United States and including 121,294 prescriptions, Gathercoal reported that 65.19 per cent of the ingredients in these prescriptions were

official in the U. S. P. X, 7.92 per cent were in the National Formulary, 16.05 per cent were proprietary specialties and 10.84 per cent were unofficial items. About the same time the author of this paper found by a study of the catalogues of physicians supply houses that a preponderant proportion of the ingredients used in their formulas were official in the U. S. P.

The Pharmacopœia of the United States was founded by physicians in 1820 as a therapeutic guide to the profession. It has endeavoured to maintain that position for more than a hundred years. Its preparations were the basis for the teaching of therapeutics in medical schools for almost a century and now they constitute the large majority of those therapeutic agents recommended by the American Medical Association in *Useful Drugs* as a present-day therapeutic guide for medical schools.

PHYSICIANS AND THE PHARMACOPŒIA

The Pharmacopœia invites the physicians of the country to assist in maintaining it as a reliable guide to the medical profession in the field of therapeutics. If items now official are unreliable they should be deleted; as important new remedies are developed these should find a place in the Pharmacopœia by 'interim revision'.

It is believed that, with a study of the ingredients official in the new Pharmacopœia, especially when supplemented by the National Formulary tablets, ampules and elixirs of U. S. P. drugs, including such preparations as Elixirs of the Bromides, of Barbitol, Phenobarbital and Aminopyrine respectively, and the Sprays and Jelly of Ephedrine, physicians will find a wide range of medicines for practically every therapeutic need.

OFFICIAL MEDICINES IN HOSPITAL TREATMENT

Emphasis should also be placed on the restriction of routine hospital treatment to official medicines whenever possible, since this has been demonstrated to be a policy which is scientifically and economically sound.

PRESCRIPTION WRITING BY HOSPITAL INTERNS

This programme for the hospital has within it another possibility of far-reaching significance. It is realized that the medical student has little opportunity in his crowded curriculum to become familiar with official titles or even to gain practice in prescription writing. Insufficient information and training in these two fields as well as the use of certain types of hospital formularies and lack of co-operation between the house and visiting medical staffs help to explain the failure to write more prescriptions for official medicines. This is being recognized by a number of hospitals, and both medical and surgical interns are being given regular training in the use of official medicines and in prescription writing. The appreciative response, where this course has been well conducted, is gratifying and is apparently justifying itself by the increased efficiency and ability of the younger physicians having this added training. The medical staffs of many hospitals have developed their own 'formulary' as an aid in the efficient and economic use of medicines within the hospital. The prescriptions in such a 'formulary' should never be given by numbers, as this practice has led to both carelessness and mistakes. In the coupling of such a 'formulary' the official titles of drugs, chemicals or preparations, or their official abbreviations, should be used so that the younger physicians on the staff may become increasingly familiar with these established medicines.

THE PRICE OF A PRESCRIPTION

The price of a prescription is no small item for consideration in the total cost of medical care. It should be the basis for a complete understanding and must be established on a sound and economically correct foundation.

It is proper that the patient should pay for the medicine and that it should not come out of the physician's fee, for that is not economically sound and

leads to numerous abuses. Many physicians to-day are being persuaded to start the practice of office dispensing. There are conditions in which this is justified, as in a country district where there are no prescription-filling facilities; but that it introduces the possibility of many complications must be conceded, and most physicians return to prescription writing as soon as financial pressure is relieved.

However, to return to the price to be charged for the prescription: when the pharmacist is called on to utilize his professional skill and equipment in supplying the medicine ordered by the physician or when he has prepared the medicines beforehand in his laboratory, using his training and equipment, there is justification for including a reasonable professional fee in the price to be charged the patient.

THE REFILLING OF PRESCRIPTIONS AND THE GIVING OF COPIES

An argument sometimes advanced against the writing of prescriptions is based on the belief that the patient often continues the use of the medicine long after it was intended by the physician by having the original prescription refilled and by even giving copies of the prescription to friends.

If a physician prefers that the prescription shall not be refilled except on his order, it is the common practice to add to the prescription the abbreviation 'non rep.' and his injunction will be honoured by the pharmacist.

This 'non rep.' order should never be printed on a blank prescription. It has a different significance when written on the prescription by the physician. The pharmacist can assist by attaching a special label to the filled prescription indicating that it is nonrefillable. In such cases 'a copy' of the ingredients should not be placed on the package.

SUMMARY

The welfare of the patient is often aided by the administration of a properly selected medicine. A distinctive prescription, written for the needs of a specific patient and using official drugs or preparations whenever these are available, is desirable.

The skilled professional pharmacist can often be helpful in the selection and combination of medicines.

The judicial use of the 'non rep.' order on prescriptions and the employment of official titles will assist in the control of objectionable self-medication.

Reviews

A SYNOPSIS OF HYGIENE.—By W. W. Jameson, M.A., M.D. (Aberd.), F.R.C.P., D.P.H., and G. S. Parkinson, D.S.O., M.R.C.S., L.R.C.P., D.P.H., Lieutenant-Colonel, R.A.M.C. (Retd.). With a Section on Personal Hygiene. By G. P. Crowden, M.Sc., M.R.C.S., L.R.C.P. Fifth Edition. 1936. J. and A. Churchill, Limited, London. Pp. viii plus 623, with 17 illustrations. Price, 21s.

THE general excellence of Jameson and Parkinson's *Synopsis of Hygiene* is better shown by the fact that a new edition is called for every two or three years, and that it has now reached its fifth edition, than by anything that the reviewer can say about it. It remains for him to endorse the general opinion and to indicate the general scope of the book and the extent to which it should be of value to those working under Indian conditions, instead of the English conditions for which it is primarily written.

The book is a synopsis of all those subjects, excepting bacteriology and chemistry, studied during a course for the Diploma in Public Health. It is not possible to put more than a synopsis of nine months' work into one volume, but the authors have made this volume of great value as a general textbook by documenting it fully with references to official and other publications with which the reader can fill in the very solid outline they provide. In most similar textbooks it is usual to find the main emphasis laid on such routine matters as food inspection, provision of water supplies, removal of refuse, with a minor emphasis on the epidemiology of disease. In the book under review the epidemiology and control of disease, the causation and prevention of maternal and infantile mortality, and the essentials of healthy living in the form of food, clothing and personal hygiene, warmth, light and air are the main interest of the authors; it is their treatment of these subjects which puts their work far in advance of others. They deal fully with the routine duties of a medical officer of health, but it is a pleasure to see these in their proper perspective as a means to an end rather than as an end in themselves.

All those conditions which a medical officer of health in India might be expected to meet are dealt with in this volume, accurately and with sufficient references to original sources to enable the student to elaborate his knowledge, but it is natural that those which are principally tropical should be less fully described than those which are principally found in temperate countries. Most diseased conditions are both tropical and temperate, their incidence differing only in degree,

and the work should therefore be invaluable in India, but it should be regarded as an invaluable addition to, and not a substitute for, a training in tropical hygiene. There must be few medical officers engaged in public health practice who can afford to dispense with its help.

The chapter on public health law, which includes the Consolidating Public Health Act passed only a few months ago, gives a very full and clear account of the state of the law in England and is an almost essential guide to anyone wishing to understand it. To the worker in India this chapter is mainly of interest as an indication of the general lines along which we may hope to direct public health law in India when it is fully realized how necessary a legal backing is to any effort to improve the public health.

G. M.

ENDOCRINOLOGY IN MODERN PRACTICE.—By William Wolf, M.D., M.S., Ph.D. 1936. W. B. Saunders Company, Philadelphia and London. Pp. 1018, with 252 figures. Price, 42s.

Of the many contributions made during recent years to our knowledge of medicine, perhaps the most significant are those pertaining to the domain of endocrinology. The physiology and biology of the glands of internal secretion are now better understood, the chemical nature of the hormones is better recognized, and active extracts or pure principles have been isolated from many of them. The various diseases or symptom complexes associated with dysfunction of one or more of these glands can therefore be studied with much more precision than was possible at the beginning of this century. The literature on the subject however is so vast that it is difficult even for the specialist or the research student to keep abreast of all useful information. Dr. Wolf's book is an attempt to present the clinical phase of endocrinology in a 'comprehensive and authoritative manner, yet free from burdensome, technical and theoretical considerations'. The author is to be congratulated on what he has achieved.

The book has been divided into three major sections. The first section deals with the anatomy, physiology and biology of the glands; this is followed by a description of the disease entities in a manner and sequence most likely to be met by the physician during the course of his practice. In the second section is set forth the endocrine aspects of 'non-endocrine' diseases and the third part is taken up with the procedure and methods to be followed in the diagnosis of the various endocrinopathies. The various theories and hypotheses

are not presented with a bias, but sympathetically and stimulatingly. A very useful feature is the introduction of summaries of the whole subject in a tabular form at the end of each chapter. This facilitates rapid review of the salient points. Not less important for the everyday practitioner is the chapter on commercially available endocrine products and the treatment of the various endocrine disorders; the author appears to be generally optimistic and has shown a good deal of reliance on 'substitution therapy'. In view of the too frequent disappointments encountered, many practitioners treating such conditions would not be in agreement with the author on certain points in this regard.

The book is full of pertinent information on the subject. The remarkably lucid presentation keeps the enormous number of items correlated in an almost perfect unit and the student is properly orientated at all times. The book is worthy of the attention of all interested in endocrinology in modern practice.

R. N. C.

A TEXTBOOK OF SURGERY.—By John Homans, M.D. Fourth Edition. 1936. Charles C. Thomas, Springfield, Illinois, U. S. A. Pp. x plus 1267. Illustrated. Price, \$8.00

THE opinion of a consulting physician would probably be that this work raises surgery to the dignity of medicine, and indeed, in interest, literary style and soundness of doctrine it deserves to rank with the classics. The illustrations, mostly by Willard C. Shepard, remind one of the beautiful woodcuts in Bland-Sutton's books, and are enlivened by occasional bright sketches of the way in which certain accidents happen. The publishers are evidently proud of their handiwork, for a quaint little notice gives technical details of the paper, printing and binding.

In the orthodox way, chapters on general principles are followed by regional descriptions, and a very pleasing feature is the inclusion, at the beginning of each chapter, of a short historical note, which whets the reader's appetite for the heavier, but always attractive and digestible, fare to come.

New matter includes an excellent chapter on the sympathetic nervous system, which is pleasantly cautious, and among other things points out that pre-sacral neurectomy for megacolon in boys may render them impotent later, while the chapter on amputations and plastics is a model of well-reasoned soundness. The chapters on the central nervous system are some of the best in this, or in any book, and in them one detects the master hand of Harvey Cushing. Certain other sections might be brought more up to date, for instance, in the article on cleft palate there is no mention of post-Langenbeck operators such as Veau and Wardill, and the hormone treatment of undescended testicle and chronic interstitial (cystic) mastitis is not referred to. The treatment of fractures might be described as bloodless with a Böhler influence, and, although bone-plating is not mentioned, many English and Indian surgeons feel that the method has its uses.

All the information required in a first-class textbook is given, but given with such charm and humanity that the student hardly realizes he is learning, so learns all the better, for this is no full catalogue of facts and methods, but a real attempt to make the reader into something nobler than a mere licensed craftsman, and to give him that true insight into the cause of things without which he cannot hope to cure them.

H. W.

AN INTRODUCTION TO SURGERY.—By R. Morison, M.D., F.R.C.S. (Edn.), F.R.C.S. (Eng.), M.A., D.C.L., LL.D., and C. F. M. Saint, C.B.E., M.D., M.S., F.R.C.S., F.R.A.C.S. 1935. John Wright and Sons Limited, Bristol. Pp. ix plus 367. Illustrated. Price, 15s.

It was a pleasure to find this book to be really what its title implied and not another addition to the

plethora of cram books which already exist on the subject.

No attempt has been made to achieve completeness nor to furnish academic detail; the aim is to introduce the atmosphere and general principles of surgery to the student and to encourage him to think out his problems. The text is written in an easy yet impressive style and is augmented where emphasis is necessary by accounts of personal cases and by well-reproduced illustrations.

The student commencing his clinical work would be well repaid if he were to study this book. He would get a foundation for his future study which the heavy standard works do not attempt to supply yet, which is so important for his proper appreciation of the subject.

J. C. D.

HANDBOOK OF SURGERY.—By E. C. McKie, M.B., Ch.B., F.R.C.S. (Edn.). 1936. E. and S. Livingstone, Edinburgh. Pp. xii plus 699. Illustrated. Available from Messrs. Butterworth and Company (India), Limited (Publishers), Calcutta. Price, Rs. 9-6

THIS is a book offering the student and post-graduate a means of quick revision of the whole subject of surgery within a small compass. Excess of detail has been avoided and the information given is accurate, if not very full. The writer has succeeded in avoiding the tabular type of presentation so familiar in other cram books, and has made his text quite readable.

As the arrangement is the classical one, the book could be used in conjunction with any of the larger works. Such a practice is, however, of doubtful value. It would be better to restrict the use of books of this type to rapid last-minute revision.

J. C. D.

ROENTGEN INTERPRETATION. A MANUAL FOR STUDENTS AND PRACTITIONERS.—By G. W. Holmes, M.D., and H. E. Ruggles, M.D. Fifth Edition. 1936. Henry Kimpton, London. Pp. 356. Illustrated with 243 engravings. Price, 22s. 6d.

THE authors have found it necessary to produce a fifth edition of this small book on radiological diagnosis so it must be in fairly constant demand.

The first chapter is devoted to shadows caused by various superimposed bodies, such as those in the clothes, also calcifications, deposits of metallic salts and other causes of shadows that may lead one astray, and the second chapter deals with anatomical variations in the skeleton. These chapters are short but will repay careful study by the novice as they will serve to guide him past the principal pitfalls into which an inexperienced observer is liable to fall in interpretation of x-ray plates.

The next five chapters deal with the bones and joints and include the appearances caused both by injury and disease. In the chapter on pathology the reviewer was startled to observe a figure of the head of the tibia labelled, 'Coccidiosis in a child', but on reference to the text he was relieved to find that the paragraph with the introductory word *Coccidiosis* in black type began as follows:—'*Coccidiodes* is a chronic granuloma due to the *Oidium coccidium*.....'. It is difficult to see how 'coccidiosis' can be derived from this name as it is always the generic and not the specific name that is employed in manufacturing names for parasitic diseases. One does not of course expect a specialist in radiography to be conversant with the niceties of parasitological nomenclature, but it is felt that it would have been possible to have avoided such an error as the above without much trouble. Such mistakes are regrettable because the influence of the printed word is so powerful on the minds of many uncritical readers. Do we not constantly hear the remark, 'It must be right; I saw it in a book' no matter how impossible the statement under discussion may be?

The chest, the gastro-intestine and the genito-urinary tract each occupy a separate chapter and there is a short chapter at the end describing the use of the fluoroscope.

This is a short book as it only occupies 356 pages counting from the title page to the end of the index and much of the space is covered by text-figures. It is little more than a summary of the subject, but it is a very good summary and is all that a general practitioner or student needs to keep him abreast of the advance of radiological diagnosis, and it offers the chances of amplifying its pages by a useful bibliography at the end of each chapter.

The price is perhaps somewhat high for a non-essential book to the general practitioner but this is probably unavoidable as the numerous beautiful photographic reproductions necessitating the use of heavy art paper must have inevitably led to high cost of production.

CUSHNY'S TEXTBOOK OF PHARMACOLOGY AND THERAPEUTICS OR THE ACTION OF DRUGS IN HEALTH AND DISEASE.—By C. W. Edmunds, A.B., M.B., and J. A. Gunn, M.A., M.D., D.Sc., F.R.C.P. Eleventh Edition. 1936. J. and A. Churchill Limited, London. Pp. 808, with 70 illustrations. Price, 25s.

THE original author's connection with this well-known book ceased with the preparation of the eighth edition which appeared in 1924 as he died suddenly in 1926. The present joint authors have been responsible for the three subsequent editions.

All books on pharmacology to keep up to date have perforce to be revised when the official lists of drugs are so dealt with and the tenth edition appeared in 1932 to bring it into line with the new edition of the British Pharmacopœia in that year and this edition has appeared to keep pace with the United States Pharmacopœia which was revised this year.

Apart from the omission of some drugs and addition of others necessitated by the changes the book on the whole maintains its former character. The authors complain that a strictly logical and scientific arrangement of the substances used in therapeutics is not possible. We are in complete agreement with this statement but feel that possibly atebirin and plasmoquin might have been more logically dealt with than placed at the end of the section under quinine and under the page heading of that drug.

It is also felt that tetrachlorethylene, a drug of proved anthelmintic value, might have been included in this section and that hexylresorcinol should have been mentioned here also, and the only comment on its anthelmintic value not included in the discussion of this drug as a urinary antiseptic.

The value of carbarson as a drug in the treatment of chronic amœbiasis is not in our opinion sufficiently emphasized and the bibliography on this section does not include any of the references to the work of Chopra and his assistants on this subject.

This is one of the best books in the English language on the uses and actions of drugs and is strongly recommended by the reviewer as a standard book for students or for reference by practitioners. The above criticisms are offered in the hope that the book might be still further improved for workers in the tropics if the authors kept closer watch on the work done in tropical countries and recorded the results in a little more detail.

MANUAL OF PHARMACOLOGY.—By the late W. E. Dixon, M.A., M.D., B.S., B.Sc., D.P.H., F.R.S. Eighth Edition, revised by W. A. M. Smart, M.B., B.S., B.Sc., M.R.C.S., L.R.C.P. 1936. Edward Arnold and Company, London. Pp. viii plus 483. Illustrated. Price, 18s.

SINCE its first appearance, the *Manual of Pharmacology* by Professor Walter E. Dixon has been considered as one of the standard textbooks on the subject and has enjoyed a wide popularity in the English-speaking countries. The untimely death of Professor Dixon prevented the appearance of a new edition for over seven years. Pharmacology has made such rapid strides during this period that a revised

edition, bringing the subject matter up to date and in line with the modern development of the subject, was urgently called for. The publication of the eighth edition, revised by Dr. W. A. M. Smart, is therefore very opportune and will undoubtedly be welcomed by students and teachers alike.

To write a new book is admittedly a difficult task; to revise and edit a book from the master hand of Professor Dixon is not only a difficult but a delicate task. The pruning, addition, alteration and 'touching up' have all to be carried out with a good deal of tact and judgment, and it is not always easy to decide as to where to stop. Dr. Smart is to be congratulated for the careful way in which he has performed his duties. He has recast, rewritten and revised a considerable portion of the text, so much so that to a casual reader the book would appear to be a new one, not a new edition of the original Dixon. A careful reader however would find plenty of evidences of the original and the personality of the man behind the book is still to be found.

One feature which attracts immediate notice is the introduction of much organic chemistry. This is very helpful in bringing into prominence the interrelationship between chemical constitution and pharmacological action. Extensive changes were naturally needed in those topics in which there have been important and noteworthy developments. Chief among these are sections dealing with hypnotics, pre-anæsthetic medication, ergot, respiratory drugs, antipyretics, synthetic and anti-malarials. As is common with almost all the books written by Western scientists, topics of interest to students in the tropics have not received exhaustive attention. The vitamins, hormones, sera and vaccines have all been treated in a small chapter. In view of the growing field of utility of these preparations, it would seem desirable to allot a little more space to these subjects.

The book is well printed and the arrangement and grouping of the various headings and sub-headings leave nothing to be desired. We have no hesitation in recommending it to students and medical practitioners, in fact, we consider that it should form part of every medical man's library in this country.

R. N. C.

A TEXTBOOK OF PHYSIOLOGY.—By H. E. Roaf, M.D. (Toronto), D.Sc. (Liverpool), M.R.C.S., L.R.C.P. Second Edition. 1936. Edward Arnold and Company, London. Pp. viii plus 679. Illustrated. Price, 21s.

THE manner of presentation as well as the amount and selection of matter are both important in the compilation of a textbook of physiology. The author presents the subject in a manner different from the usual tradition. The book is divided into four parts. The first and second parts deal with the mechanical and chemical activities of the living organisms; the third with the mechanism and regulation of these activities through the nervous system and the endocrine organs; and the last with the maintenance of the individual and the reproduction of the species. This arrangement is likely to give a connected idea of what physiology aims at teaching. Useful information has been incorporated and tiresome details avoided. The diagrams are clear and the description of the experiments is simple. On the whole this is a useful book for the student and we congratulate the author and the publisher on its production.

P. D.

APPLIED DIETETICS: THE PLANNING AND TEACHING OF NORMAL AND THERAPEUTIC DIETS.—By F. Stern. 1936. Baillière, Tindall and Cox, London. Pp. xxi plus 263, with 52 tables. Illustrated. Price, 16s.

It will be many years before we can hope to get a textbook on dietetics written to meet conditions in India and containing tables based on analyses of local foodstuffs. We must therefore turn to those of other

countries. The supply of these is increasing rapidly but each of the examples that we have seen has its own individual features that will make a special appeal to each different class of reader.

In this new book there are a number of outstanding features, but one that will appeal to the teacher and sanitarian is the number of the diagrams, drawings and tables that will be useful both for the lecture theatre and the popular health exhibitions.

The first part of the book consists of chapters on daily requirements, the construction of normal and therapeutic diets, and the education of patients on normal or therapeutic diets. Part II consists of tables designed to simplify the computation of a diet. Part III gives dietary outlines which form the basis of a normal diet and of diets for various abnormal and diseased conditions. Part IV gives simple menus for healthy people at different ages and on different economic scales, and for certain diseased conditions, such as nephritis and diabetes, colitis and constipation.

The reader will find this a very handy and practical textbook on dietetics. Its usefulness in India will be limited only by the fact that reference is not made to many of the important foodstuffs of this country and that the tables of nutrition requirements will also be misleading and will have to be modified for Indians. However, seven-eighths of the information given is directly applicable to local conditions and the book will form an invaluable addition to the library of the physician or sanitarian.

L. E. N.

DISINFECTION AND STERILIZATION.—By E. C. McCulloch, M.A., D.V.M., Ph.D. 1936. Henry Kimpton, London. Pp. 525. Illustrated with 53 engravings. Price, 25s.

THE information embodied in this volume is of immense interest to those who are engaged in the study

of bacteriology, systematic or applied. Although the subject is of a highly technical nature yet the author must be congratulated on his lucid way of dealing with the various chapters of this book, so much so that the entire work reads more like an interesting novel than a highly complex volume on bio-physico-chemistry.

The history of the use and development of antiseptics from the days of the ancient Egyptian kings to the present twentieth century is of great interest: in fact, the whole of the first chapter will appeal to even a lay person and the chronological order of arrangement is worthy of an historian of no mean merit. The subsequent chapters deal with the various factors which keep down the bacterial population in nature and the best means of utilizing heat, light, electricity and chemicals in sterilization and disinfection: of these the chemicals have been dealt with more fully and their comparative efficacy and modes of action analyzed and explained very thoroughly. As a book of reference for the worker in bacteriology this volume may be called a veritable mine of information: for those who are engaged in the administration of public health the chapters on water purification and sewage treatment offer many practical and valuable hints which can be adopted or slightly modified to suit local conditions. The undergraduate student of bacteriology will perhaps find the book heavy reading, but those who intend taking up higher studies in the subject will be well advised to keep a copy of this book, for herein will be found many points of interest which are not usually found in a standard textbook of bacteriology. The last chapter of the book is very instructive in so far as it deals with the almost futile use of antiseptics in medical or surgical practice without actually dogmatizing on any particular method of treatment. The few suggestions and hints laid down are very rational and strictly scientific.

K. P. B.

Abstracts from Reports

REPORT OF THE SUDAN MEDICAL SERVICE FOR THE YEAR 1935

Subjects of special interest

(a) Interim report on kala-azar investigations (by Sir Robert Archibald, Adviser in Medical Research)

In view of the possibility of kala-azar being conveyed from man to man by blood-sucking insects, it was important to ascertain whether leishmania parasites were present in the peripheral blood of cases of kala-azar in all stages of the disease. A thorough examination of 190 peripheral blood films taken from 31 cases of kala-azar showed parasites present in two cases = 6.4 per cent. In each the parasites were found phagocyted within a polymorph and mononuclear leucocyte respectively. One case contracted the disease in the Fung, the other case in Eastern Mongalla.

Nasal swabs from 22 cases showed leishmania in seven cases = 31 per cent. In two cases heavy infections were found.

Examinations of faeces, centrifuged urine and conjunctival secretions of cases of kala-azar proved negative for leishmania.

Examinations of viscera of dogs, cats, ground-squirrels, fowls, gekkos and lizards in kala-azar villages proved negative for leishmania parasites.

Examinations of large numbers of wild sand flies, mosquitoes, house-flies, lice and bed bugs caught in kala-azar huts and in the kala-azar ward of Singa hospital showed no evidence of leishmania parasites or their cultural forms.

Epidemiological data collected strongly indicate 'the contact factor' with or without an intermediate host as an important factor concerned in the endemology of a disease which, so far, has not appeared in epidemic form.

Examination of all contacts of cases of kala-azar is an essential measure in the control of the disease; it will serve to detect early cases as well as cases which are not seeking medical treatment; such cases, as proved at Daragil, assist in maintaining infection in villages.

In two instances young infants born of mothers suffering from kala-azar showed no signs of the disease four to six months after birth.

No evidence has been found or exists that dermal leishmaniasis occurs in the Fung or Rahad district.

Oral leishmaniasis is probably more common than is suspected. One case admitted to hospital for necrosis of the jaw showed leishmania in a slightly enlarged spleen, numerous parasites in nasal swabs, and one parasite phagocyted in a leucocyte was found in the peripheral blood.

Animal experiments

Grey monkeys have been infected by subcutaneous inoculation. Leishmania parasites have been found in nasal swabs taken 21 days after intraperitoneal inoculation.

Grey monkeys have been infected by nasal swabbing and nasal spraying of infective material. Two out of five healthy monkeys contracted kala-azar infection when placed in contact with five experimentally infected monkeys in an insect-proof room.

(b) Vitamin 'A' prophylaxis for cerebro-spinal meningitis (by Dr. N. L. Corkill)

In 1934 an epidemic of a severity hitherto not experienced swept Eastern and Central Kordofan and, when it closed with the advent of the rainy season, its spread had reached the neighbourhoods of Dilling and Heiban.

A further epidemic affecting the whole Nuba area was forecasted for the next dry season (commencing

October 1934) on three grounds, (a) the dispersal of carriers on the abolition of the quarantines, (b) the lack of recent meningitis experience in the population as a whole, and (c) the economic depression since 1931 coupled with an apparent neglect of food crops by the Nubas for the more attractive money crop of cotton, the growing of which had developed at a phenomenal rate.

On account of (c) it was decided to attribute the unprecedented severity of the 1934 epidemic to sub-nutrition and to apply an experiment to assess the value, if any, of Mellanby's 'anti-infective vitamin A' as a prophylactic.

The expected epidemic occurred, the vitamin concentrate Essogen was procured and two experiments were conducted.

The results were inconclusive but favourable rather than unfavourable to the drug being of value.

There is, however, a further point in its favour. The incidence rapidly declined in medicated communities as a whole, as compared with the controls as a whole, but the mortality rate in the medicated was greater than that in the controls, the explanation probably being that persons on the border line of susceptibility were saved from infection by vitamin and thus mortality became more concentrated in the marasmic remainder. Now, on analysing the data amassed during the epidemic it was found that, when incidence increased but mortality decreased, a factor was at work increasing susceptibility, and conversely that, when incidence decreased but mortality increased, a factor increasing susceptibility was being removed. Assuming this to be a valid law and applying it to incidence and mortality comparisons as between the medicated and the control groups, it is seen that in the former a factor increasing susceptibility was being removed; this factor would appear to be a deficiency of vitamin A.

Viewing these results in academic isolation, they do not constitute a strong case for the use of Essogen. Viewing them in relationship with what is known of the diet and diseases of Sudanese and what has been published, they form a practical justification for further experiment and the immediate adoption of the routine use of a vitamin-A concentrate in outbreaks of meningitis and pneumonia amongst prisoners, troops and institutions of the nature of schools.

REPORT OF STACK MEDICAL RESEARCH LABORATORIES

By DR. E. S. HORGAN

The Stack Medical Research Laboratories, built in 1927-28 as a memorial to the late Sir Lee Stack, formed the bacteriological unit of the Wellcome Tropical Research Laboratories organization. With the retirement of the director and the subsequent decentralization, the laboratories became an integral part of the Sudan Medical Service from the 1st April, 1935, thus forming the nucleus of the present laboratory services. The activities of the laboratories may be classified under three main heads:—

RESEARCH

Having been incorporated in the Sudan Medical Service, it is proposed, in the future, not to regard the laboratory as a detached organization, but to collaborate with the medical service, as a whole, in more extensive field operations. The first problem to receive attention along these lines will be malaria in the Gezira in relation to which an entomological survey has already commenced.

ROUTINE ACTIVITIES

These may be divided into (a) routine examinations of specimens and (b) preparation of vaccines. Routine specimens are sent in from all parts of the Sudan, but as might be expected a considerable proportion of such come from the Khartoum-Omdurman thickly-populated area. A recent feature is the large and steady increase in specimens sent in from provincial hospitals and dispensaries, while the total examinations have doubled within the last five years. There is sometimes a certain tendency to lay undue emphasis on an increase of routine examinations in evaluating the efficiency of a

tropical research laboratory. Such increases are no doubt very gratifying but there seems a certain risk in allowing them to choke the essential research activities of such a laboratory.

In a country like the Sudan the fundamental importance of short range research demands a close liaison between it and routine examinations, the latter forming its raw material but at the same time it is equally important to hold a balance between them. The increase of routine work in the laboratory for the past five years has been an inevitable feature of the expansion of medical activities through the Sudan, but it is hoped, in the near future, by raising the standard of the small hospital laboratories throughout the country to decentralize considerably the volume of such work, in particular the simpler examinations of clinical pathology, and so leave the central laboratory more opportunities to deal with the important or difficult tests and the problems arising therefrom.

Another point in the work of a tropical laboratory which seems to have received insufficient attention is the statistical significance of negative results. It is perhaps not fully appreciated by home workers that the standard routine methods often give very misleading and fallacious results in tropical conditions, and hence an important element in routine research is the elaboration and the application of more accurate methods.

EDUCATIONAL

(a) *Improved training of Sudanese laboratory assistants for the hospital laboratory service.*—For some years past it has been the practice to send intelligent hospital orderlies to the laboratory for training in the simpler routine tests and after a period of tuition to send them out to the various provincial hospitals. Owing to the increasing demands for such assistants it was not always possible to give a sufficiently full course and frequently the candidates sent in were most unsuitable for laboratory work.

The present service of Sudanese laboratory assistants has been organized as follows: Every member of the existing service will undergo a full course of training for the Stack Laboratories, irrespective of the length of time he has already been in the medical service. The period of tuition proposed is at least four months. Their present educational standard is somewhat varied but all can read and write Arabic, a few have a good primary school education, and some have a certain knowledge of English. Tuition is carried out in Arabic by the British laboratory assistants under the superintendence of the assistant director of laboratory services and is entirely practical. The course is divided into two sections—(i) clinical pathology on which at least three months must be spent, special emphasis being laid on parasitological examinations of blood, faeces and urine, and the common bacteriological staining methods, viz, Gram's, Neisser's, Ziehl-Neelsen, etc., (ii) a practical course in the methods of dealing with infected materials; use of antiseptics, cleaning glassware, plugging tubes, making swabs and capillary pipettes, sealing ampoules, etc. This part is demonstrated by the head Sudanese laboratory attendant under the direct supervision of the senior British assistant. At the end of the course, a practical examination is held by the assistant director of laboratory services, and successful candidates recommended to the director, medical service, for promotion as classified officials.

To ensure the maintenance of this standard as far as possible, all Sudanese assistants will be brought back in due rotation for 'refresher' courses.

Hospital laboratories. The equipment is being standardized, all stains, reagents, etc., being the same as those used in the Stack Laboratories and issued in solution, as it has been found by experience that the local preparation of stains such as Leishman's is quite hopeless.

(b) *Teaching of medical students.*—The Stack Laboratories are in close association with the Kitchener School of Medicine and, in addition to courses in

pathology, bacteriology, and parasitology given by the bacteriologists, a small pathological museum is maintained. Post-mortem demonstrations are also given, but, owing presumably to local prejudices, the number of autopsies is lamentably small and their rarity remains a weak feature in the education of the medical students. An attempt to lessen the difficulty is being made by increasing the number and variety of unmounted pathological specimens which can be handled by the students. It is not pretended that this is an efficient substitute for fresh post-mortem specimens. Furthermore, owing to the high temperature in Khartoum for a large part of the year, the preservation of mounted or unmounted specimens is a task of considerable difficulty and no really satisfactory method has yet been found for the preservation of colour.

Rabies research. Staining methods:—

It is doubtful if any of the usually recommended methods gives altogether satisfactory results with formalin-fixed brains.

The value of formalin however in a country like the Sudan lies in the ease with which a solution can be prepared, as it is supplied to all hospitals and dispensaries as an ordinary issue. Consequently, attention has been devoted to methods which will give the best histological differentiation with formalin-fixed brains. Trials are now being made with the Safranin-Fuchsin method of Lépine which is claimed to give excellent results for demonstrating Negri bodies.

Owing to the suggestive results of several recent workers that the mid-brain or medulla is more suitable for examination for Negri bodies than the usual hippocampus an investigation is now being made into this point on all brains received for routine examination.

Yellow fever.—Survey work was continued in two directions:—

(1) *Examination of livers.*—Routine instructions have been sent to all senior medical inspectors in the southern and western Sudan to send in specimens of liver from as many cases as possible of jaundice or fever of unknown origin dying within eight or nine days. Viscerotomy, as recommended by Dr. Soper of the Rockefeller Foundation, have been supplied to all important stations in the south and have proved of great value in obtaining specimens of liver from cases where a post-mortem examination was refused.

During the year 30 specimens of liver were received—29 of which were negative for yellow fever.

The following was the only suspicious case and serves well to illustrate the difficulty of diagnosis in a doubtful case from a viscerotomy specimen of liver and the possible fallacies that may arise through the sole use of this method.

The history of the case was as follows:—

Patient was a male about 25 years of age who came direct to Malakal from Liri Nuba taking four days on the journey. He remained well for 16 days and then complained of severe epigastric pain and vomiting. Three days from the onset of symptoms he was admitted to hospital with intense jaundice and in a comatose condition. There was no fever while he was in hospital nor history of any before admission, nor did he vomit while in hospital. Spleen and liver not enlarged. Blood slide negative for malarial parasites but positive for *Filaria bancrofti*. Urine contained albumin (+ +), blood (+ +) and ova of *S. haematobium*. Cerebrospinal fluid showed no abnormalities. After two and a half days in a comatose condition he died. An autopsy being refused, only a viscerotomy specimen of liver was taken. Examination of this showed a widespread fatty degeneration of moderate degree and areas of eosinophil necrosis. These areas were not definitely mid-zonal. What appeared to be Councilman bodies were present and certain of the nuclei showed suggestive changes.

Owing to the suspicious changes in the liver, the slide was sent to Dr. G. M. Findlay, Wellcome Bureau of Scientific Research, London, for his opinion.

He reported as follows:—

'The liver slides which arrived yesterday were extraordinarily suggestive of yellow fever and had they

come from a case in West Africa or one with a more suggestive clinical history, I should have had little hesitation in saying that they were from a case of yellow fever. If the history is correct and the man was only ill a short time, the intense jaundice is not characteristic of yellow fever. It usually only comes on in yellow fever cases about the eighth or ninth day. The absence of temperature is also peculiar, though it is difficult to imagine that such extensive necrosis could occur in the absence of all fever. There are quite a number of Councilman lesions in the liver and also, I think, intranuclear inclusions'.

Taking all factors into consideration it seems extremely doubtful if the case was one of yellow fever, in spite of the suggestive histological appearances.

(2) *Collection of sera for mouse-protection tests.*—The serum is pipetted off and sent in sealed ampoules to the laboratories where it is forwarded on to Dr. G. M. Findlay for the mouse-protection tests.

It might be mentioned that owing to strong recommendations Behring's venules were first tried but proved completely useless, the blood becoming rapidly hæmolyzed and arriving as a thick syrupy fluid useless for any serological test.

Serum from 29 cases was sent to London, of which nine showed protection; eight of the positive cases were from the southern Sudan, and one from Wad Medani. Investigation of the last showed that the patient was a cattleman from the western Sudan and the result therefore is of little significance.

Cases of jaundice of unknown ætiology.—During and previous to the yellow fever survey of the past two years numbers of cases of a clinical syndrome of unknown origin have been reported. The symptoms are usually moderate fever (in most cases), deep jaundice, vomiting in some cases, albuminuria is usually present but, in most cases, appears to be of slight degree. In some of the fatal cases leucocytosis (polymorphonuclear) is present, in one fatal case the white count shortly before death being 50,000 per c.mm., but this is unusual. A considerable number of such cases died but, as it is very difficult to obtain any reliable record of the total number, it is impossible at present to say if the mortality is high.

Pathology. All examinations of blood, urine and faeces have been negative. Mouse-protection tests have also given negative results. On several occasions it has been possible to investigate small outbreaks more fully and the possibility of leptospiral infections has been borne in mind but in no case have leptospirae been isolated, and adhesion tests, kindly carried out by Major H. C. Brown of the Wellcome Bureau of Scientific Research, have always been negative.

Pathological lesions. The microscopic appearances of the liver are very variable and often appear to bear no relation to the intensity of the jaundice and other symptoms. As a rule however there is well-marked necrosis, in some cases so extreme that all semblance to liver structure is lost. Hæmorrhagic changes are uncommon and infiltration of portal tracts and necrosed areas by lymphocytes is variable. Fatty changes are rare and there is no eosinophilic degeneration of the cytoplasm of affected liver cells. The spleen is usually greatly congested and, in some cases, there is a central necrosis of the Malpighian bodies. The kidneys are often congested and show changes in the convoluted tubules ranging from a cloudy swelling to a definite necrosis of the epithelium; the latter is, however, uncommon. Bile staining of the necrosed tubules may be present.

The resemblances, especially in the liver, between these cases and cases of an obscure infective disease associated with jaundice occurring in Nigeria have often been noted but until something more is known of the ætiology of the Sudan cases further speculation on this point is profitless.

Kala-azar.—Since the discovery by Forkner and Zia of the occurrence of Leishman-Donovan bodies in nasal and tonsillar swabs these are being examined as a routine diagnostic procedure. Positive results are

frequently observed even in early cases where serological tests are negative but the value of the operation is at present *sub judice*.

THE BRITISH GUIANA MEDICAL ANNUAL
FOR 1936. TWENTY-SIXTH YEAR OF ISSUE.
EDITED BY G. H. STEVEN, M.B., Ch.B. (EDIN.),
AND A. G. COIA, M.B., Ch.B. (EDIN.).
PRINTED BY 'THE ARGOSY' COMPANY,
LIMITED, BRITISH GUIANA

This is a collection of papers by practitioners in the colony, and it is also apparently the local organ of the British Medical Association as it includes a synopsis of the meetings of this body since the publication of the previous issue. The volume also contains fourteen papers which are mainly of clinical interest.

In a preparatory note the editors 'have again to apologize for the interval since the last publication'. Reference to our back numbers shows that number twenty-five of this 'annual' covered the year 1932 and was reviewed by us in September 1933. If the more regular appearance of this booklet cannot be assured those responsible for its appearance would be well advised to alter its title.

REPORT ON THE PUBLIC HEALTH ADMINIS-
TRATION OF BURMA FOR THE YEAR 1935
INCLUDING ADMINISTRATION OF VAC-
CINATION IN 1935-36

Cholera 0.57.—The death rate from cholera this year is the highest since 1930; it is 0.50 over the previous year and 0.51 in excess of the five-year mean. The year opened inauspiciously, for by the 1st January this disease was present in severe epidemic form in the Irrawaddy division. Early in January, it appeared in Pegu and Tenasserim divisions. The epidemic in Pegu division was limited in extent but that in Tenasserim assumed grave proportions. By May every division in the country was infected in varying degrees. The seasonal prevalence of the outbreak was most unusual for Burma. Whereas in previous years a cholera epidemic was usually limited to the months of April to July, the epidemic of 1935 increased in intensity between January and April, declined somewhat in May and June and increased again in July and August. After that it declined steadily towards the end of the year. The highest mortality was in the Tenasserim division, especially in Mergui district.

The disease was mainly prevalent in rural areas, and the difficulty of communications made the task of the public health staff a very formidable one. The cadre of epidemic sub-assistant surgeons employed for epidemic duty was increased from 19 to 27 in January, and this strength was maintained for most of the year. From the reports of these sub-assistant surgeons, an idea can be gained of the hardships and obstacles which had to be overcome in reaching the far-flung areas to which the epidemic spread. The enthusiasm and keen sense of duty of the epidemic staff is reflected in the satisfactory total of 576,216 inoculations which they carried out. This is a record figure for Burma, the greatest number of inoculations in any previous year being 186,435. Regrettable though the necessity may have been for the inoculations, the response of the people to this modern method of protection is very encouraging, and is a striking example of the changing outlook of the populace towards the causes and prevention of this particular epidemic disease.

Anti-cholera measures.—Inoculation with anti-cholera vaccine and the purification of water supplies as far as practicable were the two main measures relied on. Intensive propaganda was carried out by the epidemic sub-assistant surgeons of this department and by the hygiene publicity officer. That fact combined with the intensity of the outbreak and the increasing recognition on the part of the people of the value of cholera inoculation, resulted in a record number of inoculations being performed. A close enquiry was made regarding

any cholera deaths occurring amongst those who were inoculated. Figures have been collected from four districts relating to 241,713 inoculated individuals. As far as can be ascertained only 18 persons died of cholera amongst this inoculated population. Eight of these died within 72 hours of inoculation, *i.e.*, before immunity could be expected to be established. These figures are at present being subjected to a close scrutiny in co-operation with the statistical department of the Rangoon University, and it is hoped to publish them shortly, with conclusions drawn. The districts in which the largest number of cholera inoculations was carried out were Mergui 58,771, Pyapón 56,682, Maubin 49,849 and Pakókku 46,605.

As far as possible, the holding of *pweds* and festivals was restricted, but between the months of March and April this is a matter which presents some difficulty. Bleaching powder was used extensively in the purification of water supplies.

Smallpox 0.10.—The rate is 0.03 below the previous year and 0.02 below the five-year mean. Every district, except Kyaukpyu and Sandoway, reported mortality from this cause. As usual, the period March to May produced the greatest number of cases, and the lowest prevalence was in November. An analysis of the deaths by ages shows that 7.77 per cent of the deaths occurred among children under one year, 22.11 per cent among children between one year and under ten years and 70.13 per cent among people over ten years. The Vaccination Act which enforces primary vaccination in children who have attained the age of six months, has been in force in Burma since 1883 in the towns and since 1923 in the rural areas. The vast majority of the people get vaccinated as children and the value of primary vaccination is recognized generally. Until the necessity for revaccination is similarly appreciated, the annual mortality among people over ten years of age will be difficult to avert.

Plague 0.11.—It is satisfactory to record that this rate is the second lowest recorded in the province for this disease, since it first appeared in epidemic form in the year 1905. It is 0.08 below the previous year and 0.03 below the five-year mean. The improvement has been in the urban areas. As usual the sea-board districts of Arakan, Tavoy and Mergui were free. Other districts recording no mortality from plague were Hanthawaddy, Myaungmya, Thayetmyo, Pakókku, Kyaukse and Lower Chindwin. November to March was as usual the period during which the disease was most prevalent, 1,013 deaths out of a total of 1,312 occurring in these months.

Anti-plague measures.—The use of cyanogas for the destruction of rats was introduced to the province in July 1934 and by the end of 1935 there were 49 towns and 20 districts in possession of the necessary apparatus together with a supply of cyanogas. A large number of the health staff in the municipal and rural areas had by that time been trained in the use of this poison. Throughout the year this method of rat destruction was used extensively. Although it is impossible to ascertain the number of rats destroyed, the reports received state that there was a perceptible decrease in the rat population in the areas in which cyanogas was used. An improved type of cyanogas pump fitted with a cut-out device came on the market. With this pump the operator, after the requisite amount of cyanogas has been pumped into the rat burrow, is enabled to continue pumping air so as to ensure the effective distribution of the gas throughout the rat burrow system. This results in more effective use of the gas, and at the same time in an economy in the amount of cyanogas expended.

Fevers 7.31.—This figure is 0.47 below the previous year, but is 0.30 in excess of the five-year mean. Any decrease in this figure is most welcome, for this disease group accounts for 35.78 per cent of the total mortality in the province. The reduction of 0.47 per 1,000 corresponds to 5,741 less actual deaths. Mortality from this group of fevers is mainly reported from the rural areas where the village headmen are the registrars.

The vast majority of cases with a rise in temperature are classified under this heading. In spite of this unsatisfactory diagnosis, there is no doubt that malaria causes a considerable portion of these deaths. The highest number of deaths from fever occurred in the month of December, and it is in that month that the highest incidence of malaria was also recorded. The lowest number of deaths was recorded in the month of February.

Enteric fever 0.22.—As the diagnosis of this disease is so often dependent on accurate bacteriological examination, it is believed that the total of 315 deaths recorded during the year falls short of the true mortality. Blood specimens for culture are taken by medical practitioners in only the minority of cases of fever, and for that reason many enteric infections are probably missed. Other factors against the detection of enteric cases are the remote chances of isolating the organism from the blood after the first week of the disease, and the fact that patients frequently wait for an appreciable time before calling in a medical man.

Dysentery and diarrhoea 0.53.—The provincial rate is 0.11 over the previous year and 0.06 higher than the five-year mean. Associated with the outbreak of the cholera epidemic, there was also an increase in the number of deaths reported from dysentery and diarrhoea. There was undoubtedly in the rural areas a certain amount of confusion regarding diagnosis, and it is probable that a certain number of the early cases of cholera was ascribed to this group of dysentery and diarrhoea. Some headmen are averse to diagnosing cholera on account of the alarm it may cause amongst the inhabitants, or perhaps, in some cases, on account of the extra work and trouble it may entail. The highest mortality from dysentery and diarrhoea was, as usual, recorded in the month of July and the lowest figures were recorded in February.

Respiratory diseases 0.99.—This is 0.08 lower than the previous year's figure and 0.01 below the five-year mean. The highest mortality occurred in December and the lowest figures were recorded in February. Each year there is marked preponderance of deaths amongst males, the proportion in 1935 to the deaths amongst females being 146 to 100.

Gout.—The disease is reported from a number of districts mainly in the hilly areas such as the Shan villages in Thandaung township in Toungoo district, the Kachin Hill Tracts in Bhamo district and among the Hill Karens in Salween district. In the Southern Shan States it is reported from amongst the hill inhabitants of Kengtung subdivision. Treatment in the civil hospitals has been carried out extensively in some districts such as Myitkyina 1,726 cases, Northern Shan States 6,673 cases, and Mogók and Thabeitkyin hospitals 564 cases.

Yaws.—This disease is very prevalent along the valley of the Tenasserim river in Tavoy and Mergui district. It is also prevalent in Victoria Point subdivision and Bokpyin township in Mergui district. No treatment was carried out in these areas during 1935 owing to lack of funds.

Leprosy.—Colonies for the housing, feeding and treatment of lepers were maintained at Mònywa and Minbu during the year.

This department considers that in the establishment of leper colonies lies the most effective measure for the control of leprosy in Burma. A colony is much cheaper to establish and to maintain than an asylum. It has an advantage over clinics in that in the colony the treatment can be taken to the segregated lepers, instead of expecting the individual lepers to go for treatment to the nearest hospital clinic which is frequently some miles distant. Were sufficient colonies started throughout the province, they would exercise a marked effect in checking the spread of leprosy amongst the general population, and in addition they would exercise a marked effect on the control of pauper lepers. The class of leper who now leaves his village to go and beg in the towns would have a colony to go to where

his housing and food would be assured, where the conditions of life would approximate to those of his village and where he would get regular treatment leading to cure or early arrest of his condition. He would be spared the experience of being regarded as an outcast and having to descend to the level of a pauper.

Snake-bite.—The mortality due to snake-bite has become a subject of public interest in the last couple of years, as evidenced by questions asked in the Legislative Council and articles on the subject in the newspapers. Up to 1935 the mortality figures from snake-bite were collected under the same heading as deaths due to wild-beasts. For 1935, snake-bite figures have been compiled separately and these show that 2,186 deaths occurred during the year from this cause. Only 76 deaths were in towns the balance of 2,110 being in the rural areas. The provincial death rate was 0.18 and the rural and urban death rates were 0.20 and 0.05 respectively. The Russell's viper is said to be the commonest cause of death.

The highest seasonal incidence was in the month of December. A pamphlet in Burmese containing advice on the prevention and treatment of snake-bite was issued in January 1936, from the Hygiene Publicity Bureau of this department, and its distribution, especially in rural areas, is being continued.

Conservancy.—During the year 90 bored-hole latrines were constructed at Einmè and 17 at Thayetkôn in Myaungmya district. The cost of these latrines was met by the district council. This is an example which might well be followed by the district councils in those areas where bored-hole latrines can be constructed. In Kyaiklat township in Pyapôn district a number of bored-hole latrines were made and are reported to be working satisfactorily. A few bored-hole latrines were constructed in some of the villages in Insein township for demonstration purposes.

Rural health unit, Hlègu.—This is the sixth year in which the unit has been in operation. As in the previous years the work undertaken included the collection and study of vital statistics, health education, vaccination, school medical inspection, maternity and child welfare work, control of acute communicable diseases, refuse and sewage disposal, improvement of water supplies and abatement of nuisances.

Registration of vital statistics has been markedly improved. The birth rate of 35.51 recorded during the year is the highest since the inception of the unit. The mean birth rate for the five years prior to the starting of the unit was 16.89 per thousand. In order to encourage birth registration a new and attractive design of birth registration certificate was introduced during the year. This has captured the villager's imagination and has acted as good propaganda for early birth registration. Improvement has also been brought about in death registration. The death rate during 1935 was 20.20. The five-year mean rate prior to the unit's inception was 12.72. The infant mortality rate of 124.84 for 1935 is the lowest since the inception of the unit. There were 14 maternal deaths giving a ratio of 6.01 per thousand registered births and 74 stillbirths giving a ratio of 3.17 per hundred live births. The vital index of the area was 175.79.

Of the acute communicable diseases, there was one case of cholera who recovered and seven cases of small-pox with one death. Primary and revaccinations were carried out among 4,950 persons during the year. By the end of the year 68 per cent of the population in Hlègu township were protected by either primary or revaccination. Of the less acute communicable diseases, there were 26 cases of chickenpox, four cases of measles and 60 cases of whooping cough. Lectures, health conferences, lantern talks, cinema shows and school health talks totalled 280 with an approximate total attendance of 11,795. There were 247 infant and maternal welfare clinics held at the two centres in Hlègu and Dabein with a total attendance of 1,771. The nurse carried out 3,682 home visits. The two midwives conducted 413 confinement cases and paid 1,651 prenatal and 1,564 postnatal visits.

During the year there were 36 registered vernacular schools in the Health Unit area; of these 17 were provided with individual drinking watercups, cupracks and properly protected water receptacles. Ventilation in the schools was sufficient, but in the majority of the schools the light was found defective. Improvement was, however, noticed in six schools. Regular school medical inspection was made in 22 schools and 1,156 children were given a thorough physical examination. Among this number, 380 or 32.87 per cent were found free from physical defects.

The unit continued to assist in leprosy work in the township so far as time and personnel permitted.

The number of laboratory examinations carried out was 89. Oil of chenopodium was administered to 2,453 persons for the treatment of round worm infection, and of the 1,972 cases in which the results were known 96.7 per cent were relieved. *Gambusia affinis* were distributed to four tanks in three villages as an antimosquito measure, and 100 malarious patients received 1,883 cinchona febrifuge tablets.

Measures for the improvement of environmental sanitation were continued as in previous years. A total of 395 inspections was made of wells and tanks and suggestions were given for their improvement; seven wells and two tanks were provided with force pumps and 34 wells were chlorinated. Sanitary inspections of food establishments and commercial premises totalled 1,528. Anti-rat measures were carried out as a routine and 355 rat holes were fumigated with cyanogas, 490 holes blocked and 5,742 rats were trapped or poisoned. During the year 1,556 lorry loads of refuse were removed to the dumping grounds in Hlègu and Dabein.

The policy of encouraging the householder to construct bored-hole latrines was continued and during the year 201 additional bored-hole latrines were provided. In 20 per cent of these the householder contributed part of the cost. The total number of bored-hole latrines constructed by the unit up to the end of 1935 was 1,828 in 17 villages. Under the supervision of a public health inspector the construction of bored-hole latrines was carried out in four villages in Insein township for demonstration purposes, and a number of boring implements were kept on hand for loan or for sale to local bodies. The total cost of constructing a bored-hole latrine in Hlègu is Rs. 7-14 which includes a reinforced concrete squatting plate of the latest design; the householder provides the superstructure. From the experience in this township and from data collected over a period of six years, when used with reasonable care a bored-hole latrine will last for four years for a family of five to eight persons. The constant use of a well-fitting cover prevents all fly breeding; but where this precaution is neglected and fly breeding occurs, a half inch layer of old motor oil or crude oil effectively stops the nuisance.

In its capacity as a field training centre for practical training of public health personnel, the unit undertook during the year the training of one assistant district health officer, nine sub-assistant surgeons and three public health inspectors. Six students for the Government of Burma License in Hygiene, eight students of the health visitors training class and fifteen students of the medical college visited the unit to gain practical knowledge in dealing with public health problems. Since its inception the unit has undertaken the practical training of 171 public health personnel.

Cinchona febrifuge tablets.—As usual, these were manufactured in the Rangoon jail, from where they were distributed to district treasuries either for issue on payment or for free issue when authorized. During the year 3,826,980 tablets were sold by the treasuries, which is an increase of 455,400 tablets over the sales of 1934. However, the increase was not general and was mainly confined to the Southern Shan States. The average consumption of cinchona febrifuge per head of population rose from 0.87 grain in 1933 to 1.00 in 1934 and to 1.20 in the year under review.

Maternity work.—In 1935 there were 34 midwives employed by 11 voluntary child welfare societies, and they attended 6,095 confinements, while 186 midwives employed by municipalities and district councils attended 19,447 confinements. In the towns of Burma 30.21 per cent of the total births were attended by midwives employed by child welfare societies or local bodies, and the corresponding figure in rural areas was 2.73 per cent. A large number of midwives are engaged in private practice, but the figures of the cases attended by them are not available, nor are those of the cases attended by private medical practitioners.

After the close of the year the Rural Health Unit, Hlègu, started an experiment of employing midwives on a reduced pay, and permitting them to charge fees proportionate to the means of the patient. An official receipt is given for every fee that is charged. It is believed that the people do not resent paying a moderate charge. The giving of an official receipt by the Health Unit obviates any abuse. The Hlègu system is still at the experimental stage, but the reports are encouraging. If it is a success, it might be followed by the district councils in the province, as it will enable the local bodies to employ an appreciably increased number of midwives without increasing the expenditure.

Health education.—In recent years there has been a marked development in this form of health activity. In 1935, there was a further appreciable increase in the amount of lecturing work. An encouraging sign was the many demands received from local bodies, public institutions and voluntary welfare organizations for literature on health subjects, for the loan of the Red Cross Society's health exhibits and for the services of the hygiene publicity officer.

The post of the hygiene publicity officer was kept vacant owing to financial stringency, but sub-assistant surgeon U. Tha Saing continued to carry out very effective health propaganda work.

[These abstracts only give a brief outline of the many activities of this very live public health department and detailed study of this report would repay any provincial health officer.]

ADMINISTRATION REPORT OF THE MUNICIPAL COMMISSIONER FOR THE CITY OF BOMBAY FOR THE YEAR 1935-36. VOLUME II. ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER FOR 1935

Review of the year.—The number of live births registered during the year was more by 5,139 than the number of deaths that took place in the city. This excess of births over deaths was equivalent to 4.4 per 1,000 population calculated on the census of 1931 and was recorded five times in succession. Before 1931 there was no such excess since 1866, the year in which birth records were instituted. The number of live births registered was 34,428, being 704 more than in 1934, 8,795 more than the average of the last ten years 1925 to 1934 and the highest on record since 1866. The birth rate calculated on the census population of 1931 was 29.6 births per 1,000.

The total number of deaths from all causes was 29,289, being 1,919 more than in 1934, 3,278 more than the average for the last five years (1930 to 1934) and 1,737 more than that for the preceding decennium (1925 to 1934). The death rate per 1,000 of census population of 1931 was 25.2 as against 23.6 in 1934 and 23.7 the rate recorded for the decennium 1925 to 1934.

There was only one death from plague during the year as against 31 in 1934 and 89 the average of the last ten years 1925 to 1934. Smallpox was in an epidemic form and caused 1,248 deaths as against 152 in 1934 and 846 the average for the last decennium 1925 to 1934. Cholera was registered as the cause of 13 deaths (including 8 imported) against the same number in 1934 and 17 less than the average for the ten years 1925 to 1934. Influenza was prevalent in a mild form in the city during the year and caused 72 deaths as against 98 in the preceding year and 86 the average

for the last decennium 1925 to 1934. The deaths from diseases of the respiratory system numbered 10,642, being 586 more than in 1934 and 617 more than the average of the last ten years 1925 to 1934. Tuberculosis accounted for 1,929 deaths as against 1,856 in 1934 and 1,604 the average for the preceding decennium 1925 to 1934.

Ninety-seven deaths were due to malaria, being four less than in 1934 and 170 less than the average of the last decennium (1925 to 1934). There were 1,389 deaths from ague and remittent fever as against 1,397 in 1934. The average number of deaths for the last ten years (1925 to 1934) from malaria was 267 and from ague and remittent fever 1,569. The deaths among infants under one year of age numbered 8,455 against 8,253 in 1934 and 7,474 the average for the last ten years 1925 to 1934. The rate of infant deaths per 1,000 births registered was 245.6 as against 291.6 the mean of the preceding decennium.

Compared with the decennial averages (1925 to 1934) the total number of deaths shows an increase of 1,737, the principal increase in the mortality being 402 deaths under smallpox, 617 under respiratory diseases, 241 under diarrhoea and dysentery, 153 under measles, 325 under tuberculosis, 70 under cerebro-spinal fever and 54 under enteric. On the other hand there was a decrease in deaths under plague by 88, under influenza by 14, under ague and remittent fever by 180 and under malaria by 170.

Prevention of infantile mortality.—The work which is being done in Bombay for the reduction of infant mortality may be described under the following heads:—

(i) Visits by the municipal district nurses for the purpose of getting into touch with prospective mothers and for discovering cases of sickness especially among women and children and unvaccinated children; for enquiry into the condition of new born infants; and for giving instruction by homely talks as to the care and rearing of children.

(ii) Attendance on confinements.

(iii) Provision of necessities and comforts during the lying-in period.

(iv) Maternity homes.

(v) Infant welfare centres and infant milk depots.

Municipal nurses.—The number of municipal nurses employed is ten, one being attached to each of the ten district registrars' offices. They visit daily the localities and the *chawls* inhabited by the poor and help to diffuse and popularize elementary knowledge of the principles of health and hygiene and to carry such knowledge into the homes and lives of the ignorant; they give advice on the prevention of disease and the care and up-bringing of infants and bring to the notice of the authorities unregistered births, unvaccinated children and cases of sickness; they also persuade prospective mothers to go to the maternity homes provided for them free. Where this provision is not taken advantage of, they attend on the women in their own houses providing them with bedding for the confinement, and with food in the shape of milk and bread during the first seven days of the puerperal period. The visits of the nurses are frequently the means of bringing to the municipal dispensaries sick persons who would otherwise either not know the existence of the facilities provided or knowing would, through indifference and apathy, neglect to benefit by them. These visits are doing much good and are welcomed and appreciated by those for whose benefit they are paid.

Infant welfare society.—This society has been doing good work. At the end of the year there were seven centres, three maternity homes and one crèche at DeLisle Road. Each centre is in charge of a lady doctor (full time), a graduate of the Bombay University, under whom there is a supervisor and a health visitor; the former is a fully qualified, diplomaed nurse and the latter is a qualified maternity nurse.

The supervisor looks to the distribution of milk and assists the lady doctor at the clinics and in advising mothers on infant management. The health visitor

visits her district and persuades the expectant mothers to take advantage of the maternity home in the city and to bring their babies to infant welfare centres for milk and treatment.

The society provides through its centres and homes (i) advice and instruction to mothers as to infant management; (ii) treatment to infants for minor maladies; (iii) baths to infants; (iv) free distribution of milk to the deserving expectant mothers and infants, and at reduced rates to those who can afford to pay; and (v) confinements at the maternity homes.

REPORT OF THE DIRECTOR OF MEDICAL AND SANITARY SERVICES, HONG KONG, FOR THE YEAR 1935

GENERAL REMARKS

In the absence of some general system of registration of sickness, the only sources of information available for gauging the state of the public health in this colony are the returns relating to deaths, the notifications of infectious diseases and the records of Government and Chinese hospitals. Judging from the death returns the health of the colony was not quite so good as that of the previous year. The crude death rate was 22.90 per mille as compared with 20.93 for 1934.

Respiratory diseases accounted for 41.62 per cent of the total deaths; the percentage for 1934 was 39.97. The principal diseases causing deaths were broncho-pneumonia, pulmonary tuberculosis, bronchitis, infantile diarrhoea and diarrhoea.

The overcrowded houses, the expectorating habits of the people, and poverty furnish sufficient explanation for the prevalence of respiratory troubles.

Malaria.—This disease which in the early days of the colony was the great cause of death and from which Hong Kong derived its reputation of unhealthiness has now practically disappeared from the populous centres of Victoria and Kowloon as the result of the destruction of the breeding places of the carriers through efficient drainage. There is still some malaria in the outskirts of the two towns and a considerable amount in the rural areas of both the island and mainland.

Investigations have proved that swamps, ponds and other collections of water in the open plains are more or less harmless and that the real danger lies within mosquito flight distance of the foot of the hills and of valleys where collections of spring water in pockets, pools, swamps and streams form the breeding places of *A. maculatus*, *A. minimus* and *A. jeyporiensis*.

Why it is so we do not know, but spring water which has not lost its sparkle does have an attraction for these three species. As a rule such water has a faint acid reaction due to dissolved carbonic acid gas. When it loses its CO₂ and becomes flat it ceases to attract.

For many years the chief vector in the colony and new territories was believed to be *A. maculatus*. *A. maculatus* is a carrier but is of far less importance in the spread of malaria than *A. minimus* and *A. jeyporiensis*.

It appears that species of mosquitoes, like races of men, can under different conditions of climate and surroundings develop differences in habits and tastes for food. *A. maculatus* in Malaya readily takes human blood and is a very potent agent in the spread of malaria. In Hong Kong, where it is very prevalent, it seems to prefer animals to humans and its importance as a vector of paludism is much less pronounced.

Here as in Malaya disturbances of the soil often result in the formation of small collections of water which for reasons unknown attract the malaria mosquito and in which they deposit their eggs. The breaking of the soil is not a direct cause of malaria but a predisposing factor in a chain of events which favour the spread of the disease.

Pulmonary tuberculosis.—This disease continues to rank second to broncho-pneumonia as the principal cause of death. It is probable that some of the cases of the latter were of tuberculous origin. There is need for more hospital or infirmary accommodation for

tuberculosis patients, especially for those of the poorer classes.

Smallpox.—Every year in the cold season this disease manifests itself in outbreaks which are sometimes sporadic, sometimes epidemic. Whatever the prevalence there is always a tendency for the morbidity rate to decline or disappear with the advent of summer. In the year under review there were 61 cases and 44 deaths. Eighteen cases only were treated in hospital the remainder did not come under the notice of the authorities until after death.

The Chinese have a preference for vaccination in the spring as being the auspicious season, and for a month or two after Chinese New Year the Chinese public dispensaries are crowded with children waiting to be done.

The majority of Chinese still hold the opinion that the herbalist treatment of smallpox gives better results than the methods adopted by practitioners qualified in Western medicine. An analysis of the statistics of (a) the Tung Wah Infectious Diseases Hospital where only herbalist treatment is carried out and (b) the Government Infectious Diseases Hospital where Western treatment only is provided shows that this view is not correct. Calculating on the figures for the last 25 years the death rate at the Tung Wah was 47.2 per cent while that at the Government institution was 15.25 per cent.

Plague.—For the last six years no cases of plague have been reported in Hong Kong. The disappearance of this disease not only from the colony but from the greater part of China and its decline throughout the world are due to factors which are not understood.

Cerebro-spinal fever.—The disease is most prevalent in the cold weather. It dies down when the real summer heat sets in and people sleep more out of doors at night thus lessening overcrowding. Of the 110 cases reported, 54 or 49.09 per cent proved fatal. Ever since the severe outbreak of this disease, which occurred in 1917, a supply of serum, made at the Bacteriological Institute from the local strains of meningococcus, is kept in stock. This serum gives very good results when used early in the disease.

Enteric.—Cases of this disease are notified throughout the year, but there is usually some increase in the number reported during the summer months. The cases are usually sporadic and the source of infection is seldom discovered. Three hundred and nineteen cases were notified with 95 deaths as compared with 212 in 1934 with 65 deaths.

Leprosy.—Though leprosy is a notifiable disease very few cases are notified. The number of lepers in the colony is not known but assuming that the incidence rate is the same as that of the neighbouring countries the total number cannot be less than 500 and may approach 1,000. To many, these figures will appear to be exaggerations, nevertheless they are accepted by all who are authorities on the subject and have taken the trouble to make the necessary enquiries.

Rabies.—Ten cases of this disease were reported during the year. Three cases occurred in humans, the remainder in dogs. The human cases occurred in Kowloon. There were no cases on the Island of Hong Kong. Two of the human cases had been treated with anti-rabic vaccine before the appearance of the symptoms. All were fatal.

REVIEW OF THE REPORT ON THE WORKING OF HOSPITALS AND DISPENSARIES IN THE PUNJAB FOR THE YEAR 1935

THE financial position still remained such that there could be no expansion in medical relief during the year under report. The scheme for the provincialization of hospitals at district and *tahsil* headquarters remained at a standstill and the total number of medical institutions was practically unchanged. A new hospital was, however, constructed at Abohar and the Rai Bahadur Amar Nath Tuberculosis Institute was added to the Mayo Hospital, Lahore. The number of beds increased

by 107, and there was some increase in the number of inpatients, but the total number of patients treated decreased from 14,024,499 to 13,858,928. The main reason for this decrease appears to be that malaria was less prevalent than in the preceding year owing to diminished rainfall. A heavy call on the medical resources of the province was made as a result of the Quetta earthquake, and the department rose to the occasion in a very creditable manner. A number of medical officers, nurses and dispensers were sent to Quetta and special accommodation for patients therefrom was provided in the principal hospitals of the province. The number of dispensaries decreased by two and the development of rural dispensaries remains stationary.

The expenditure of the department increased from 47 lakhs in 1934 to 49.88 lakhs in 1935, the increase being mainly accounted for by new buildings and the annual increments of the staff. As usual little income is raised from fees, but voluntary contributions amounted to Rs. 1,49,305. Government gratefully concur with the Inspector-General of Civil Hospitals in his acknowledgment of the generous gift of Rs. 1,00,000 by Rai Bahadur Seth Kishor Chand Maheshwari of Amritsar for the establishment of a maternity home at Amritsar. Another example of local enterprise is the construction of a tuberculosis sanatorium at Samli in the Murree Hills by contributions from private persons and local bodies under the ægis of the Red Cross Society.

The Mayo Hospital, Lahore, maintained its high reputation, and had to meet the brunt of the strain on the medical resources of the province due to the influx of patients from Quetta. The late Colonel T. A. Hughes, I.M.S., ably discharged the duties of Medical Superintendent of the hospital till he was appointed Principal of the King Edward Medical College in November, 1935. It was hoped that his rare gifts would have been of special value in the latter post, but continued ill health obliged him to take leave and his subsequent death in England was a great loss to the college and the province.

The civil hospital, Amritsar, continues to be handicapped by lack of accommodation, the daily average of inpatients being far in excess of the number which it was intended to provide. It is hoped to give relief by the conversion of the old medical school building into a separate ophthalmic hospital, and the plans for the necessary alterations are under the consideration of Government. The Ripon Hospital, Simla, also suffers from the same difficulty in spite of the number of beds being raised from 56 to 70 during the year under report. The Lady Willingdon Hospital, Lahore, continues to work at full pressure and many gynæcological cases had to be refused for want of accommodation. Proposals for providing accommodation for 116 more beds are under consideration. The construction of the Teka Devi Health Centre in connection with this hospital, made possible by the generosity of Rai Bahadur Lala Amar Nath, is also now in hand. All the above-mentioned hospitals, as well as the Punjab Dental Hospital, Lahore, and the Lady Aitchison Hospital, Lahore, maintained a high standard of efficiency.

As noted in the review for the previous year, the diagnosis and relief of leprosy is engaging the attention of the medical authorities to an increasing extent, and the survey conducted under the auspices of the Punjab Branch of the British Empire Leprosy Relief Association was continued. The working of the five leper homes in the province is reputed to be extremely satisfactory and a large number of the patients treated was cured or much improved. There are also 52 leper clinics in which 578 cases were treated. The question of applying the Indian Lepers Act to the province has again been raised, but Government consider it to be impracticable at present. It has been decided, however, to proceed with a scheme for establishing a settlement for 'burnt out' cases in the Lower Bari Doab colony, to which lepers from the leper homes can be transferred, thus making room in

the homes for a greater number of active cases. The details of the scheme are under consideration.

The scheme inaugurated in 1926 for providing medical aid to women by lady doctors in separate hospitals at each district headquarters and in special female sections at each *tahsil* headquarters hospital still falls far short of achievement, but there are now 50 separate hospitals for women under the charge of lady doctors, and also 33 such doctors in charge of female sections in general hospitals. The number of beds for women increased from 3,971 in 1934 to 4,024 in 1935. At the same time there is a steady increase in the number of women doctors and the number of applicants for admission to the medical colleges and schools now exceeds the number of vacancies available. There are at present 216 women studying medicine in the various institutions, and during the year two women students qualified for the M.B., B.S. degree and 12 for the L.S.M.F. diploma. Satisfactory progress has also been made in the training of *dais* and midwives. A sum of 2 lakhs of rupees from Their Majesties' Silver Jubilee Fund has been set aside for providing a scholarship fund for the medical training of women.

THE SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH. ANNUAL REPORT FOR THE YEAR ENDED 31ST DECEMBER, 1935, JOHANNESBURG

Department of industrial hygiene.—The focus of interest in the matter of air-borne dust on the mines of the Witwatersrand has been influenced by the visit of Dr. W. R. Jones. It will be remembered that Dr. Jones had put forward an hypothesis to the effect that while most of the air-borne dust, and of the dust recovered from the lungs of those who have been exposed, was free silica as shown by chemical analysis, the majority of small particles was contributed by micaceous matter. It was also urged by him that it was the number of particles that was the dominant factor in injury to the lungs. The earliest analyses on dust recovered from lungs of sufferers from pneumokoniosis were performed some eighty years ago, and these and subsequent analyses had shown that while most of the dust recovered was contributed by free silica, plenty of other dusts could be recovered, and nineteenth century workers accepted many dusts as pneumokoniosis-producers. It was also held that while many dusts contributed to pneumokoniosis, it was only certain dusts that were associated with tuberculo-pneumonokoniosis, and that it was this association with tuberculosis that was the significant factor in the disablement and death of those exposed. Early in the present century, E. L. Collis was thought to have proved by statistical analysis that it was free silica that was the tuberculosis-facilitating dust, and tuberculo-silicosis became also a synonym for dust-phthisis since, previous to the systematic examination of employees started on the Witwatersrand in 1916, it was only *via* tuberculosis that a phthisis-producing industry was identified.

Dr. Jones' hypothesis has raised certain questions. Firstly, was he correct in suspecting that it was micaceous matter that contributed to the majority of the smallest particles? Investigations have shown that, down to the minimal size identifiable by petrological methods, say a trifle below two microns, the majority of our air-borne particles, and of those recovered from lungs, are particles of free silica. This does not settle the question since 70 per cent of the particles by number both in air-borne dust and in dust recovered from lungs are of the order of one micron and less. To attack this problem it has been necessary to attempt a method of segregating dust in terms of size frequency.

Preliminary work by the Geological Survey and the Mine Air Committee is furnishing some support for Dr. Jones' view that the proportion of micaceous matter rises with diminution in size of particles.

This leads to a second question. It is fairly generally held that free silica is tuberculosis facilitating in virtue of the fact that it is slowly soluble in the lungs, and

that this silica solute depresses the lungs ability to deal with after-coming infections. Is the micaceous matter met with in the air-borne dust on the Witwatersrand also soluble and, if so, is this solute toxic? Preliminary work on material supplied by the Geological Survey suggests that this solubility is negligible.

A third question arises. It is fairly well established that particles above three microns do not play an important part in phthisis production. It is not known what may be the minimal size at which inert (insoluble) particles cease to contribute to scar-formation. It is hardly practicable to collect a sufficient quantity of particles of one micron and below for inhalation or even for injection experiments, but one is contemplating subcutaneous and intravenous injections, also abscess-fixation experiments with a view to comparing the behaviour of free silica and micaceous particles of minute size. This is an important question: should these minute particles be free silica in considerable proportion then they should contribute to injuring the lungs owing to their solubility even if they do not contribute to scar-formation. On the other hand, should they be mostly micaceous and insoluble they may be of little importance. There is no higher incidence of simple tuberculosis among Witwatersrand miners than among the rest of the population of corresponding age-periods, which suggests that free silica dust only facilitates tuberculosis *via* preliminary scar-formation, i.e., *via* a simple silicosis. One does not meet with either simple or infected silicosis in the absence of large numbers of particles, readily visible under ordinary magnifications, when examining sections of lungs unstained or after incineration on heat-resisting slides. (Magnifications of about 400 diameters.)

BIOCHEMICAL DEPARTMENT

As in the previous year, most of the work carried out has arisen from the native diet inquiry instituted by the Chamber of Mines.

Amongst numerous strange findings, mention may be made of a plant leaf belong to the yam family (*Dioscoreaceæ*) containing no less than forty times as much iron as spinach, whilst both the bulb and leaf of another specimen were found to be exceptionally rich in anti-scorbutic vitamin, the bulb being twice (*cf.* potato usually one-half or less) and the leaf no less than twenty-five times as rich in this substance as orange juice; however, the latter plant also possesses poisonous properties, and is only used as a food when these have been removed by special treatment.

A satisfactory feature of this study of native food-stuffs has been the encouragement and co-operation we have received from several anthropologists, who have emphasized the need for such information in connection with their own work.

Further experiments have been carried out on the composition of lucerne and its suitability for human consumption, and a report on some of the conclusions arrived at has been published. Several mines are now including the plant as part of their vegetable ration, and larger amounts have been tried out in certain mine hospitals where it has been possible to study the absorption of the antiscorbutic factor by the individuals consuming the lucerne. Dried preparations of the leaves have also been further investigated; one prepared commercially by a special process contained 1.6 mg. ascorbic acid per gramme, whilst another was as high as 3.5. The former meal has been tried out with promising results in two country native hospitals, where inexpensive antiscorbutics were practically unobtainable.

Merely from the nutritional point of view there can be no doubt that lucerne occupies a somewhat exceptional place, being remarkably rich in vitamins A and C, minerals and protein; however, either eaten raw or cooked as a spinach, it is apt to be somewhat fibrous unless obtained really young and fresh. Nevertheless, the plant is so hardy and so widely grown throughout the Union, that it may well be regarded as an emergency foodstuff of considerable value which will improve the

nutritional qualities of a ration at very low cost; moreover, the leaves, when specially dried, provide a highly concentrated source of the antiscorbutic vitamin which has the further advantage of being easily transported to areas where fresh fruit or vegetables are temporarily unobtainable.

Winter malaria.—A great deal of investigation has been carried out regarding the winter carriage of malaria in Natal.

The work included spleen surveys and the dissection of mosquitoes.

The results indicated a complete cessation of mosquito-borne malaria in winter in 'A. gambiae' areas, and that malaria is carried over from one season to another in the human host. It is suggested that the treatment of malaria in winter by the administration of

quinine or other drugs would probably have a great effect on the incidence of the disease in such areas. Notwithstanding the above expression of opinion the possibilities of a low mosquito infection, in winter in 'A. gambiae' areas along the coast cannot be dismissed entirely because of the higher humidity of the air enabling *A. gambiae* to remain in habitations which is contrary to their behaviour in the more arid inland regions, and where the dryness of the air is such that although they may breed in winter they do not remain indoors.

With regard to *A. funestus* the results of investigation suggested a low, or no infection, rate among these mosquitoes in winter, plus a carry over in the human host; therefore both treatment of malaria and anti-mosquito measures are indicated.

Service Notes

APPOINTMENTS AND TRANSFERS

To be Officiating Deputy Director, Medical Services, Northern Command:—

Colonel W. H. Hamilton, C.I.E., C.B.E., D.S.O., K.H.P., vice Major-General A. W. M. Harvey, K.H.S., on combined leave. Dated 21st October, 1936.

Lieutenant-Colonel J. C. De, Superintendent, Campbell Medical School and Hospital, Calcutta, is appointed to act, until further orders, as Principal, Medical College, and Superintendent of the Medical College Hospitals, Calcutta, vice Lieutenant-Colonel T. C. Boyd.

Lieutenant-Colonel P. Banerji, on general duty at the Medical College Hospitals, Calcutta, is appointed to act, until further orders, as Superintendent, Campbell Medical School and Hospital, Calcutta, vice Lieutenant-Colonel J. C. De.

Lieutenant-Colonel J. Rodger, M.C., an Agency Surgeon, is appointed to officiate as Civil Surgeon, Sibi and Loralai, in addition to his own duties as Residency Surgeon and Chief Medical Officer in Baluchistan, with effect from the afternoon of the 7th October, 1936.

Lieutenant-Colonel P. F. Gow is confirmed in the post of Professor of Midwifery, Medical College, Calcutta, with effect from the 28th July, 1935.

In supersession of previous notification, the services of Major W. H. Crichton, Health Officer, Simla, are placed temporarily at the disposal of the Chief Commissioner, Delhi, for the post of Officiating Assistant Director of Public Health, Delhi, and Health Officer, New Delhi, and Health Officer, Area Committee, Civil Lines, Delhi, on probation for 1 year, with effect from the afternoon of the 30th September, 1936.

Major S. Smyth is appointed to officiate as Civil Surgeon, Simla East, vice Lieutenant-Colonel B. Gale, granted leave.

The services of Major H. Williamson, O.B.E., an Agency Surgeon, are temporarily placed at the disposal of the Government of Bombay, with effect from the afternoon of the 7th October, 1936.

On reversion from foreign service under the Indian Research Fund Association, the services of Major R. C. Wats, an Officer of the Medical Research Department, are placed temporarily at the disposal of the Government of Bombay for appointment as Officiating Assistant Director, Haffkine Institute, Bombay, with effect from the date on which he relinquishes charge of his duties.

The Secretary of State for India in Council has appointed to the Civil Branch of the Indian Medical Service the following officers of the Indian Medical Service, with effect from the dates noted against their names:—

- (1) Major W. Lawie. Dated 3rd July, 1935.
- (2) Major R. L. Frost. Dated 26th July, 1935.

(3) Captain P. H. Cummins. Dated 13th October, 1935.

(4) Captain W. Scott. Dated 15th October, 1935. In supersession of previous notification, Captain C. J. H. Brink is appointed temporarily as Air Port Health Officer, Karachi, on probation, with effect from the 23rd December, 1935.

In supersession of previous notification, the services of Captain J. P. J. Little are placed temporarily at the disposal of the Government of the Punjab, with effect from the 30th August, 1936.

Captain J. R. Dogra, Officiating Assistant Director, Haffkine Institute, Bombay, is placed on foreign service under the Indian Research Fund Association, with effect from the date on which he relinquishes charge of his duties.

Captain E. G. Montgomery, Civil Surgeon, Midnapore, is appointed as Civil Surgeon, Jalpaiguri, vice Captain H. A. Young, granted leave preparatory to retirement.

To be Lieutenants (on probation)

Stuart Cordingley Colbeck. Dated 1st September, 1936, with seniority 1st September, 1935.

John Herbertson Bowie. Dated 1st September, 1936, with seniority 1st September, 1935.

William Stewart Empey. Dated 1st September, 1936, with seniority 1st September, 1935.

Alastair Gowans Miller. Dated 1st September, 1936.

James Ford Thomson. Dated 1st September, 1936.

William Allen Hopkins. Dated 1st September, 1936.

Lieutenant E. H. Wallace is restored to the establishment. Dated 1st October, 1936.

LEAVE

Lieutenant-Colonel B. Gale, Civil Surgeon, Simla East, is granted leave up to the 21st March, 1937, with effect from the 3rd November, 1936, or subsequent date from which he may avail himself of it.

Lieutenant-Colonel M. Das, M.C., Superintendent, Alipore Central Jail, is allowed leave, from the 2nd January, 1937, to the 16th January, 1937, both days inclusive.

PROMOTIONS

Major to be Lieutenant-Colonel

R. S. Aspinall, C.I.E. Dated 19th October, 1936.

Captain to be Major

A. N. Chopra. Dated 17th October, 1936.

Lieutenant (on probation) to be Captain (on probation)

C. W. A. Searle. Dated 26th June, 1936.

The seniority of Lieutenant A. G. Miller is antedated to the 1st September, 1935.

The seniority of Lieutenant J. F. Thomson is antedated to the 17th March, 1936.

RETIREMENTS

Lieutenant-Colonel J. A. A. Kernahan. Dated 1st September, 1936.

Lieutenant-Colonel C. McIver, on account of ill health. Dated 2nd October, 1935.

Lieutenant-Colonel D. Coutts. Dated 1st September, 1936.

Notes

ANTIPHLOGISTINE

THIS is the time of year when pneumonia, influenza and other acute infectious fevers have their greatest incidence.

At the first sign of a 'chill', or if sore throat be present, the application of Antiphlogistine is one of the best safety-first measures.

Not only does it help to ameliorate the local conditions, but it may be the means of inhibiting the onset of more serious consequences. However, if pneumonia, bronchitis, or influenza supervene, Antiphlogistine helps to moderate the severity of the attack.

Antiphlogistine relieves congestion, eases pain and promotes comfort. The heat which it supplies over a period of many hours penetrates the tissues, encouraging the more rapid absorption of toxic products and the stimulation of a more active healing process.

It is especially valuable in the treatment of respiratory affections.

LONDON MEDICAL EXHIBITION

New Hall, Royal Horticultural Society, Westminster, S.W.1, 19th to 23rd October, 1936

THE Burroughs Wellcome and Co. exhibits again bore evidence on every side of the scientific resources of the firm and the continuous research work carried out. Amongst recent introductions, mention may be made of 'Stypven', Russell viper venom, described as the most efficient haemostatic available; 'Ryzamin-B', which consists of the concentrated and purified vitamin-containing fraction of rice polishings, having a potency of not less than 50 International Units of vitamin B₁ per gramme; and 'Eulykol' phenylethyl esters of a selected fraction of the acids of hydnocarpus oil, introduced for the treatment of lupus vulgaris. The section devoted to insulin included a display illustrating stages in the manufacture of 'Wellcome' Insulin, which is made with crystalline insulin of 100 per cent purity. Ergot preparations occupied a prominent place, and were represented by Ergometrine, the recently-discovered water-soluble alkaloid, and Ergotoxine ethanesulphonate, which was originated and introduced by Burroughs Wellcome and Co. The pioneer work accomplished by the firm in connection with digitalis was exemplified by Digoxin, a pure, stable, crystallized glucoside, isolated from the leaves of *Digitalis lanata*. Preparations of *Digitalis purpurea* included 'Diginutin', a stable solution of the total glucosides of the leaf (physiologically standardized); 'Tabloid' digitalis leaf and 'Wellcome' tincture of digitalis. In addition to vitamin concentrates such as 'Ryzamin-B', 'Tabloid' carotene, 'Tabloid' ascorbic acid and 'Tabloid' calciferol, prominence was given to 'Kepler' cod liver oil with malt extract, which continues to meet the modern demand for a natural vitamin-containing product. A wide range of serological products was exhibited. These are prepared at the Wellcome Physiological Research Laboratories, Beckenham, Kent, and include 'Wellcome' concentrated diphtheria antitoxin-globulins; diphtheria prophylactics (four types are issued); 'Wellcome' concentrated streptococcus antitoxin (scarlatina) globulins; 'Wellcome' concentrated staphylococcus antitoxin-globulins; 'Wellcome' staphylococcus toxoid for active

immunization; 'Wellcome' anti-pneumococcus sera; and preparations for carrying out Dick and Schick testing. Specimens of the wide range of 'Tabloid' medicine chests and cases, and of 'Agla' hypodermic apparatus were an important feature of the exhibits.

COW AND GATE FEEDS ROYAL BABIES

THE following interesting intimation, addressed to Messrs. Cow and Gate Limited, has just been received

from the Private Secretary to His Majesty King Ghazi of Iraq, dated 24th September, 1936, from the Royal Palace, Diwan, Baghdad:—

'I have the honour to inform you that His Majesty, my Sovereign, has been graciously pleased to grant you the title of "Purveyors to the Royal Palace" in respect of your product Cow and Gate on which His Royal Highness the Crown Prince Faisal is being fed, in appreciation of the good quality of your said product. The respective Royal Warrant will be sent to you in due course.

RUSTAM HAIDAR,
Private Secretary to His Majesty.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

RADIOLOGY OF THE HEART AND GREAT VESSELS

By J. A. SHORTEN, M.B., B.Ch., M.R.C.P. (Lond.),
B.A.O. (R.U.I.)

LIEUTENANT-COLONEL, I.M.S. (Retd.)

Calcutta

Part I

THE NORMAL HEART

THE methods used in x -ray examination of the heart and great vessels of the thorax include fluoroscopy and radiography, measurement of the cardiac diameters, and special observations after a 'barium swallow'.

Owing to the divergence of the rays from the anode of the x -ray tube, there is much distortion of the image if the tube is close to the chest; so, to get an accurate representation of the size of the heart, films should be taken at a distance of six feet, or the actual size of the heart may be mapped out on the screen by cutting down the diaphragm to give an image of the heart border on the screen about the size of a postage stamp, thus using the central ray to delineate the outline of the heart shadow. Other procedures such as cinematography and kymographic analysis of the heart movements have not reached such a stage of perfection as to justify their general use. Similarly, stereoscopic films do not help.

METHODS IN USE

I. Fluoroscopy

Great importance is now attached to this procedure, especially by British radiologists, who place greater reliance on personal screen examinations than on any of the various systems of measurements.

The procedure to be adopted is as follows :—The patient is placed standing in the postero-anterior position behind the fluorescent screen. A rapid survey of the cardiac silhouette is made in inspiration and expiration; the movements of the diaphragm and the condition of the cardio-phrenic and costo-phrenic angles are noted. An experienced observer can tell at once whether the heart is enlarged or not. The presence or absence of aneurysm of the heart or aorta can usually be quickly determined. Any abnormal bulging or pulsation should be noted. A preliminary opinion can usually be given as to what cavities are enlarged and a provisional diagnosis made. The tone of the heart muscle, and whether it lifts well from the diaphragm, should next be observed.

The lung fields are then scanned for any abnormality, enlargement of the hili and opacities in the lung fields due to congestion are noted. Enlarged and pulsating branches of the

pulmonary artery, indicating disease of the pulmonary arterial system, may be seen.

The patient is then slowly turned into the right oblique position (right side of the chest in contact with the back of the fluorescent screen) while a watch is kept on the borders of the heart and the great vessels. The movement should be continued until the retro-cardiac space assumes its maximal illumination on deep inspiration. This is the best position for examining the ascending aorta and left auricle. The left auricle occupies the upper two-thirds of the posterior border of the heart in this position and any enlargement backward should be noted. The posterior boundary of the retro-cardiac space is formed by the descending aorta. This is not usually seen on the screen; but aneurysm or calcification in its walls may make it visible.

Fig. 1.—Antero-posterior view.

The ascending aorta, which here has the translucent trachea on one side and the lung on the other, now claims attention. Increase in its diameter, bulging or abnormal density should be noted.

The patient is now turned into the left oblique position (left side of chest in contact with the back of the fluorescent screen). In this the posterior border of the heart, composed of the left ventricle below and the left auricle above, is inclined to overlap the anterior border of the spinal column and the patient should be turned sufficiently to clear this on deep inspiration.

The arch of the aorta lies transversely just below the shadow of the clavicle with a triangular translucent space below, between it and the pulmonary artery, which can be faintly seen. Any increase in the diameter of the aorta or increased density should be noted. In

this position the arch of the normal aorta forms a definite curve and a note should be made of any unfolding such as is seen in hyperpiesis. Also, as the anterior border of the heart here is formed of the right ventricle, a distinction can be made between enlargement of the right and left ventricle. The pulsations of the left ventricle should be carefully observed when infarction is suspected, as this condition may lead to immobilization of the affected part of the wall, or even an inward movement as the ventricle expands.

Finally, a look at the lateral view should be taken. The heart here lies at an oblique angle with the apex anteriorly, and the base above near the spine. There is a triangular space between the heart in front, the spine behind and the diaphragm below, and a similar clear

aortic arch or pulmonary artery these indentations are greatly increased. Enlargement of the left auricle may result in a large backward displacement of the œsophagus below the indentations due to the aorta and pulmonary artery.

To make a permanent record the screening set must have a tube that can be moved independently of the screen. The diaphragm is cut down to give a small central ray which is worked round the outline of the heart while the observer traces the silhouette with a grease pencil. This image can then be transferred to tracing paper.

II. Orthodiagraphy

If the special apparatus is available an orthodiagram may be made in a similar manner.

Fig. 2.

space between the heart and sternum in front. The left auricle forms the posterior boundary of the heart shadow, while the anterior border is composed of the superimposed shadows of the ventricle below and the base of the aorta above.

The patient is now turned into the right oblique position and given an ounce or so of thick barium emulsion to swallow. As it passes down, its course, outlining the œsophagus, is observed. Normally, there is a little delay on reaching the aortic arch and there is a slight indentation corresponding to this structure, just below there is another indentation due to the pulmonary artery. From here the barium shadow passes straight down to the level of the diaphragm. When there is enlargement of the

Care must be taken to mark the outline in diastole and in the same phase of respiration. This constitutes the chief difficulty and introduces the personal factor.

III. Teleradiography

Teleradiograms at two meters give a sufficiently accurate representation of the heart shadow for all practical purposes, besides giving a permanent record and eliminating the dangers of prolonged screening.

For a complete examination, skiagrams should be taken in the four positions used in screening. It will be found convenient to take oblique pictures just on completing the screen observation of the 'barium swallow', in the right oblique position. The tube is moved back to

the two meters' distance, the patient is given another mouthful of emulsion and a skiagram taken on swallowing, with the breath held in deep inspiration. The left oblique and lateral views are similarly dealt with. Finally, a postero-anterior skiagram is taken.

(1) *Postero-anterior view*

This is a standard position for a general view of the chest. In this position the left border of the cardio-vascular shadow is formed from above downwards by, (a) the aortic knuckle or knob, being the left border of the terminal part of the arch of the aorta; this curve is exaggerated in arterio-sclerosis, dilatation and aneurysm, (b) a less obvious curve due to the pulmonary artery; this is accentuated when pressure in the pulmonary artery is raised as in

Fig. 3.—Right oblique.

mitral stenosis, patent ductus arteriosus and pulmonary stenosis; on the screen the enlargement will be seen to pulsate synchronously with the aorta, (c) the tip of the auricular appendix; this is not usually seen unless there is enlargement of the left auricle, as in mitral stenosis, (d) the left margin of the left ventricle continuing the heart border down to the diaphragm. The right border is formed by the right margin of the superior vena cava above and the right auricle below. In patients of the hyposthenic habitus the heart shadow is long, narrow and central, while in the hypersthenic subject the heart shadow is broader and shorter. The right ventricle forms most of the shadow as seen from the front.

Cardiac measurements are usually carried out on skiagrams taken in this position. Many

schemes have been devised, but I will only describe the one used in my own practice. This is based on the work of Vaquez and Bordet. The two-meter skiagram is taken in full inspiration. The following lines are drawn on the heart shadow:—

(i) *Mid-line*.—A vertical line through the centre of the shadows of the spinous process.

(ii) *Transverse diameter*.—Perpendiculars to this from the point of greatest width of the heart shadow on the right and on the left. These give the right and the left median diameters, the sum of which is the transverse diameter of the heart. Normal: 14.5 to 9.5 cm.

(iii) *Length*.—A line from the point where the vascular shadow crosses the diaphragm, the usual situation of the apex, to the junction of the right auricle and the ascending aorta. This

Fig. 4.—Left oblique.

determines the length of the heart. Normal: 15.0 to 11.5 cm. The angle formed by this line with the mid-line shows the degree of rotation of the heart on its vertical axis, the greater the angle the further out will be the apex, so that mere displacement may be distinguished from enlargement. Normal: 15.0 to 11.5 cm.

(iv) *Oblique diameter*.—Lines dropped perpendicularly to the length of the heart from the junction of the left auricle and ventricle (node of no motion), and from the cardio-hepatic angle form the right and left oblique diameters, the sum of which is the oblique diameter of the heart. Normal: 10.5 to 9.3 cm.

(v) *Index of auriculo-ventricular ratio*.—This is determined by bisecting the length of the heart by a line joining the cardio-hepatic angle

on the right and the auriculo-ventricular junction on the left. The value of the upper segment (auricular) is divided by the value of the lower segment (ventricular) and the result for normal hearts is found to vary between 0.534 and 0.704. In ventricular preponderance this figure may fall to 0.200. In auricular preponderance, on the other hand, the figure may rise to 1.2.

(vi) *Left ventricle*.—A line joining the apex with the auriculo-ventricular junction on the left gives a measure of the size of the left ventricle. Normal: 8.5 to 6.7 cm. A perpendicular to this line at the point of maximum thickness establishes a bisector of its arc, and represents the thickness of the ventricular wall. Normal: 0.6 to 2.0 cm. The bisector is increased in ventricular hypertrophy.

Fig. 5.—Lateral.

(vii) *Left auricle*.—A perpendicular from the auriculo-ventricular junction on the left side to the mid-line gives a measure of the left auricle. Normal: 5.0 to 3.5 cm.

(viii) *Right ventricle*.—A line joining the cardio-hepatic angle and apex measures the size of the right ventricle. Normal: 14.7 to 8.5 cm.

(ix) *Right auricle*.—A line joining the point of junction of the right auricle and vascular arc with the cardio-hepatic angle represents the size of the right auricle. Normal: 6.5 to 3.5 cm.

(x) *Aorta*.—This is usually measured by a transverse line drawn at the widest part of the arch usually at the level of the third intercostal cartilages. Care should be taken to exclude the superior vena cava on the right. Normal measurements are 3.9 to 5.7 cm.

These measurements help considerably in determining what chambers of the heart are responsible for a particular picture of cardiac enlargement.

In addition to the above measurements an estimation of the cardio-thoracic ratio is useful. By this we mean the ratio of the transverse diameter of the heart to the internal diameter of the chest. In people of normal build this should not be more than 1:2, hyposthenic individuals may have a ratio of 1:4, and in hypersthenic people the ratio may be as low as 1:1.9.

The transverse extent of the heart shadow of course varies with the phase of respiration; but most authorities are now in favour of measurements in full inspiration.

Fig. 6.—Left oblique—measurements.

The width of the aortic knuckle may be measured by giving the patient some barium emulsion to swallow, while a skiagram is taken in the antero-posterior position. A horizontal line drawn from the indentation, where the oesophagus crosses the arch, to the point of maximum convexity of the knuckle gives the width of the knuckle. This should not exceed 3.2 cm.

The ascending aorta can also be measured in the right oblique position where it is seen between the trachea and the lung. This measurement should not exceed 3.5 cm.

(2) *Right anterior oblique position*

This is the position for examining the ascending aorta and left auricle and their relations to the trachea and the oesophagus filled with barium.

The left border of the heart shadow in this position is formed from above downwards by the arch of the aorta, pulmonary artery, right ventricle, and near the apex the left ventricle. The trachea lies in front of the arch, the left bronchus passes behind the ascending aorta and the right bronchus in front of the descending aorta. The barium-filled œsophagus passes in front of the arch and pulmonary artery, being indented by both.

The right border of the heart shadow is formed by the left auricle above and the inferior vena cava below. In the correct position, the right auricle does not enter into it. Behind the border lies the retro-cardiac space, bounded behind by the descending aorta which is not usually seen unless atheroma or aneurysm is present.

Fig. 7.—Inner border posterior part of arch outlined by barium in œsophagus.

(3) *Left anterior oblique position*

The heart and descending aorta now lie to the right of the spine and descending aorta, and therefore cross in front of the shadows of the trachea, œsophagus and right bronchus. The left bronchus passes in front of the descending aorta and pulmonary artery.

The arch of the aorta is seen passing transversely, and below this the pulmonary artery. The translucent trachea makes the latter transparent; it is not distinctly seen unless diseased. The posterior border of the heart is formed by the left auricle above and the left ventricle below. The anterior border comprises the ascending aorta above and the right ventricle below. With the patient at an angle of 45° , when the transverse diameter is at its minimum, the inter-ventricular septum will be midway between the front of the chest and the point where the ribs articulate with the spine. Also the transverse diameter of the normal heart at

this angle is half the distance between the front of the chest and the posterior articulations of the ribs with the spine. If this ratio is less than 1 : 1.9 the heart is enlarged.

The position of the inter-ventricular septum can be fixed as follows: A mark is made on the anterior margin of the trachea at the level of the bifurcation. The distance of this from the anterior border of the chest is measured and laid off on the horizontal line through this point backward. The second mark should be just beyond the spine. A second horizontal line of equal length is drawn through the widest part of the shadow at the base. The mid point of this line marks the position of the inter-ventricular septum. Measurements to the anterior and posterior borders of the heart shadow will now give the relative size of the right and left ventricles. Neither should exceed one quarter of the internal diameter of the chest in this position. This is probably the best method for measuring enlargement of one ventricle.

(4) *Lateral view*

This has been described already under fluoroscopy; so attention need only be called here to the course of the barium-filled œsophagus, which describes a long curve with the convexity backwards following the course of the spine in its upper third, but coming forward in its lower third to reach the œsophageal opening of the diaphragm. There are no local indentations such as are seen in the postero-anterior and right oblique positions.

This view is most valuable for showing enlargement of the descending aorta and left auricle.

Part II

THE PATHOLOGICAL HEART

Dilatation and hypertrophy.—Both these conditions lead to enlargement of the heart as a whole, or of individual chambers. The following classification after Parkinson gives a general idea of the significance of enlargement of individual chambers, as well as general enlargement:—

(1) *Left ventricle*

- (a) Aortic stenosis or incompetence.
- (b) Hypertension.

(2) *Right ventricle*

- (a) Mitral stenosis.
- (b) Congenital malformations (Fallot's tetralogy).
- (c) Chronic pulmonary diseases, and disease of the pulmonary artery.

(3) *Left auricle*

- (a) Mitral stenosis.

(4) *Right auricle*

- (a) Mitral stenosis.
- (b) Congenital malformations (patent auricular septum).
- (c) Tricuspid stenosis.

(5) *Pulmonary artery*

- (a) Mitral stenosis.
- (b) Congenital diseases (patent ductus arteriosus).
- (c) Chronic pulmonary diseases and disease of the pulmonary artery.
- (d) Toxic goitre.

Fig. 1.—*Mitral insufficiency.* The left median diameter shows greatest change due to enlargement of the left ventricle and lateral displacement of the apex by an enlarged right ventricle. The low index of auriculo-ventricular ratio shows preponderant ventricular enlargement.

(6) *Aorta*

- (a) Syphilitic aortitis—aneurysm.
- (b) Atheroma.
- (c) Hypertension.

(7) *General enlargement*

- (a) Pericardial adhesions.
- (b) Rheumatic disease.
- (c) Aortic incompetence with mitral stenosis.
- (d) Myocardial disease.

Having grasped the significance of the above it will now be convenient to discuss the radiological findings in the commoner diseases and abnormalities of the heart.

Valvular lesions

Mitral stenosis.—The 'back-pressure' theory, although not accepted by all, offers the most intelligible explanation of the clinical and pathological findings in this disease.

Narrowing of the mitral orifice causes increase of pressure in the left auricle which

Fig. 2.—*Mitral stenosis and insufficiency—the typical 'mitral heart'.* Note how this combines the characteristics of the two lesions.

Fig. 3.—*Mitral stenosis with beginning insufficiency* (child aged twelve). Transverse diameter of heart 10.5 cm., pulmonary field 23 cm., showing uncertainty of the 'cardio-thoracic ratio' as a diagnostic criterion. Note the prominent auricles and high index of auriculo-ventricular ratio typical of mitral stenosis and the rounding and elevation of the apex due to insufficiency.

dilates; the blood is then backed up through the pulmonary vessels to the lungs causing congestion (brown induration). This is communicated through the right ventricle to the right auricle, which having a thin wall also dilates. The left ventricle on the other hand, owing to a diminished supply of blood, actually shrinks.

The x-ray findings therefore are :—

Screen examination

(a) Enlargement of both auricles in the postero-anterior view; in extreme cases both the left auricle and the right auricle may be seen on the right border of the heart silhouette, and the enlarged pulmonary artery and conus of the right ventricle on the left border.

Fig. 4.—Aortic stenosis. Hypertrophy and dilatation of the left ventricle, with slow vigorous contractions of the heart and diminished aortic pulsations.

(b) In the right anterior oblique view with a 'barium swallow' the indentations caused by the enlarged pulmonary artery and left auricle are well seen.

Teleoroentgenogram.—One notes the prominence of the auricles—high auriculo-ventricular ratio (0.750 to 1,000)—rounding and elevation of the apex. For average measurements see table.

Mitral insufficiency.—The pathology here is due to an incompetent mitral valve allowing regurgitation of blood into the left auricle which dilates; a left ventricle which, owing to increased work, first hypertrophies and then as failure supervenes dilates. The resulting increased pulmonary resistance causes dilatation of the right ventricle.

The x-ray findings are :—

Screen examination

Postero-anterior view.—Enlargement of the left auricle and both the ventricles, and lateral

Fig. 5.—Aortic insufficiency. Note the increase in the length of the heart due to left ventricular enlargement. The heart shadow is centrally placed and the apex is lowered. The aortic width is increased. Pulsations of the heart and aorta are of increased amplitude.

Fig. 6.—Pulmonary stenosis. Characterized by increased prominence of the shadow of the pulmonary artery and enlargement of the right side of the heart. Note that the left ventricle is not enlarged, but the apex is elevated by a hypertrophied right ventricle.

displacement of the apex by the enlarged right ventricle.

Right anterior oblique view.—With a 'barium swallow' this shows backward displacement of the œsophagus due to the enlarged left auricle. *Teleoroentgenogram*—shows increased values for the left auricle, ventricle and transverse diameter of the heart with a low A. V. ratio (less than 0.500)—ventricular preponderance. For average measurements see table.

Double mitral lesions.—These combine the characteristic of mitral stenosis and insufficiency and the heart silhouette will be the resultant of the relative prominence of the two lesions.

Screen examination—will show general enlargement of the shadow due to increase in the size of both auricle and ventricles. Examinations in the right anterior oblique position with 'barium swallow' will show enlargement of the left aurifice.

Fig. 7.—*Aortitis.* Increased width of aortic shadow to the right and to the left. The 'knob' is flattened and broadened. Roentgenoscopically pulsations are of increased amplitude.

Teleoroentgenogram.—This will show increase in the right and left median diameters and the measurements of the respective cavities. The A. V. ratio may be normal depending on the prominence of mitral stenosis or insufficiency. For average measurements see table.

Tricuspid insufficiency.—This is rare as a single lesion. It is usually found in association with disease of the left side or congenital defects.

The general size of the heart is increased and the measurements of the right auricle are particularly affected. The medium diameters are increased and the apex displaced to the left. The lung fields are congested and the right diaphragm is high, due to hepatic congestion. For average measurements see table.

Aortic insufficiency.—The characteristic signs in this condition are:—(1) Enlargement of the left ventricle and (2) increased width of the aorta. When the mitral orifice is stretched to a point which admits of mitral regurgitation the signs of mitral insufficiency are superimposed,

Fig. 8.—*Hypertension.* The junction of the right auricle and vascular arc is sharply accentuated and the curve of the ascending aorta is increased. The left ventricle is frequently enlarged.

Fig. 9.—*Pericardial effusion.* For comparison with myxœdema. Roentgenoscopically cardiac pulsations are markedly diminished.

causing enlargement of the right heart, so that a progressive case shows general enlargement of the heart. For average measurements see table.

Aortic stenosis.—The characteristic change is enlargement of the left ventricle. The aorta is practically unchanged. The enlargement may be seen in the postero-anterior and left oblique views. The skiagram shows an increase in the

left median diameter, left ventricular measurement and bisector. The length of the heart is increased and the A. V. ratio low. For average measurements see table.

Pulmonary stenosis.—This condition may be associated with a defect in the inter-ventricular septum or with a patent ductus arteriosus.

The signs are exaggerated prominence of the shadow of the right side of the heart. The left ventricle is not enlarged but its apex is lifted away from the diaphragm, fluoroscopically marked systolic pulsation of the pulmonary artery and the roots of the lungs are observed. For average measurements see table.

Aortitis.—The width of the aortic shadow is increased and it bulges to the right. The aortic knuckle is flattened and broadened.

Fig. 10.—Tetralogy of Fallot. 'Coeur en Sabot'.

It is well to remember that increase in the diameter of the supracardiac shadows may be due to other causes than disease of the aorta, e.g., enlarged thymus, lymphosarcoma, and even a dilated oesophagus filled with food in cardio-spasm. Careful screening in different positions observing pulsation and the effects of a barium 'swallow' will prevent mistakes.

Aneurysm of the aorta.—The appearances due to aneurysm will vary with the size, site and shape of the pouching of the aortic wall. There may be general dilatation of the ascending or descending aorta, such as is usually seen in syphilitic aortitis. Sacculae may develop anywhere along the course of the vessel, but are most frequently seen at that portion of the arch from which springs the innominate artery. Screen examination will show expansive pulsation of the walls; which distinguishes aneurysm from other tumours of the mediastinum.

The general appearance of the heart will depend on the presence and degree of aortic regurgitation.

Hypertension.—Fluoroscopy in the postero-anterior position reveals enlargement of the left ventricle. The junction between the right auricle and the vascular arch is sharply defined and the curve of the vascular arch to the right accentuated. The shadow of the aorta is denser than normal and can frequently be seen in its whole length through the cardiac shadow. If the shadow of the aorta can be seen through that of the left ventricle the aorta is diseased.

In the left oblique position 'unfolding' of the aortic arch is frequently seen and is often one of the first signs.

Two-meter skiagrams confirm the above. The arch is seen to be elongated, projecting to the

Fig. 11.—Coarctation of aorta. Note areas of focal erosion of ribs, enlarged left ventricle and small aortic knuckle.

right and rising higher than normal and sometimes reaching the first costal arch. The aortic knuckle may be unduly prominent.

- A distinction should be made between;
- (1) essential hypertension or hyperpiesia,
 - (2) hypertension with atheroma, and
 - (3) hypertension with renal changes.

In atheroma, the walls of the aorta being thickened, the shadow cast by this vessel is often denser than that of the left ventricle. Calcified plaques may be present around the rim of the knuckle, and in the descending aorta.

When renal changes are present, in addition to the characteristics of hypertension, gross hypertrophy and dilatation of both ventricles, more particularly the left, are found with evidence of valvular insufficiency. For average measurements see table.

Thyrotoxicosis.—The characteristic change is a straightening of the left border of the heart,

which becomes concave on deep inspiration. This is best observed near the auriculo-ventricular junction.

Fluoroscopy shows increase in amplitude and rate of the cardiac pulsation.

Thyroid deficiency—myxœdema.—The outstanding feature is the enlargement of the heart. There is a general increase in all measurements, suggesting pericardial effusion. In the latter case, however, the lower limits of the cardiac silhouette are obscured, and there are alterations in contour with changes in the position of the patient. Contractions are almost imperceptible. In myxœdema the contractions are unaltered in amplitude, rate and rhythm.

Arrhythmias.—Sinus arrhythmia and extrasystoles—no alteration in size or contour.

Fig. 12.—Patent ductus arteriosus. Note enlarged pulmonary artery.

Auricular fibrillation.—The amplitude of the contractions is diminished, especially in the auricles. The rhythm is irregular, and the rates vary.

Skiograms show increased size of the auricles affecting the corresponding measurements.

Heart block.—There is a compensatory hypertrophy and dilatation of the left auricle causing increase in the left median diameter, left ventricular cavity and the bisector. The A. V. ratio is low.

Myocardial impairment.—In this all-important condition of the middle and old age, radiology can afford considerable help.

Fluoroscopically the amplitude of the contraction is much diminished. The left border of the heart is straight or concave. On turning the patient into left oblique position one may see a part of the contour of one of the ventricles, usually the left, which is immobile or moves in the opposite direction to the rest of the wall when the heart contracts or dilates.

This, if clearly evident, means infarction of the wall.

The skiagram shows the straight or concave left border and small bisector. The median diameters lie close to the diaphragm.

Congenital lesions.—It is not my object to discuss the cause of these lesions but a couple

Fig. 13.—Diagram of fetal heart. (B) Bulbus cordis. (V) Common ventricle. (P.A.) Pulmonary artery. (T.A.) Truncus arteriosus. (R.A.) Right auricle. (L.A.) Left auricle. (S.V.) Sinus venosus.

Fig. 14.—Development of left aortic arches: dotted lines indicate the vestigial arches. Numerals indicate the six arches.

of simple diagrams may help in their interpretation.

It is to be noted that in the course of development the ventricle is divided into two by the growth of the inter-ventricular septum starting from below. Similarly, the auricles are divided by the inter-auricular septum, though a communication, the foramen ovale, persists until birth.

The bulbus cordis finally disappears.

Some of the more important congenital abnormalities are due to incomplete disappearance of the bulbus cordis or incomplete development of the ventricular or auricular septa.

The segment of the aorta between the origin of the left subclavian and the ductus arteriosus is called the isthmus and has little blood passing through it in the foetus. It is consequently smaller in bore than the rest of the aorta.

Skiagrams in congenital lesions.—The changes observed concern the right side of the heart more than the left.

(1) The hypertrophied right ventricle lifts the apex away from the diaphragm (*coeur en sabot*).

(2) The conus of the right ventricle and pulmonary shadow may be absent (tetralogy of Fallot), or it may be accentuated (patent ductus arteriosus).

(3) The aorta may pass up on the right side of the spine (dextro-position).

(4) The aortic knuckle may be absent (coarctation of the aorta—right aortic arch).

Patent interventricular septum.—If the defect is large the right ventricle is hypertrophied causing a *coeur en sabot* skiagram.

Tetralogy of Fallot

This consists of:—

- (1) pulmonary stenosis,
- (2) defect in the inter-ventricular septum,
- (3) dextroposed aorta, and
- (4) hypertrophied right ventricle.

Skiagrams show

- (1) cardiac apex lifted away from the diaphragm,
- (2) concavity in the place of the shadow of the pulmonary artery, and
- (3) the ascending aorta passing up on the right of the spine and thus there may be a right-sided arch.

Pulmonary stenosis with patent foramen ovale

- (1) Right ventricle hypertrophied, and
- (2) shadow of conus prominent.

If the foramen ovale is closed the right ventricle is greatly hypertrophied, the right auricle

dilated and the shadow of the superior vena cava is prominent.

Inter-auricular septal defects

Patent foramen ovale.—The aortic knuckle is small or absent and the pulmonary shadow is enlarged.

Defects at the lower portion of the septum.—Anterior segment of mitral valve usually involved, therefore mitral incompetence or stenosis. *Coeur en sabot* may result. The hilum shadows are wide and dense and pulsate freely.

Patent ductus arteriosus.—The blood flows from the aorta to the pulmonary artery which is dilated or even aneurysm may develop.

The dilated pulmonary artery and enlarged right ventricle can be seen on screening.

Coarctation of aorta.—The dilated ascending aorta can be seen to the right of the spine. The aortic knuckle is small or absent.

In the left oblique position the aorta cannot be traced back to the spine, and its branches can be seen rising as a column from the heart shadow into the root of the neck.

Small erosions of the lower border of the posterior portions of the ribs, due to pressure by enlarged collateral vessels, are pathognomonic.

Dextrocardia.—Two forms are recognized.

(1) The heart is entirely reversed. The left ventricle forming the apex points to the right and there is general transposition of the viscera with the liver on the left and the stomach on the right. A barium meal in such cases emphasizes the changes, and it is important to note that the caecum and appendix lie on the left side. The heart is usually normal and the patient does not suffer.

(2) The heart is transposed, the venous ventricle forms the apex and lies on the right side. There is no transposition of the abdominal viscera. There are usually other abnormalities as well, such as patent ventricular septum.

[In writing this paper, the author acknowledges the help he obtained from *Recent Advances in Cardiology* by East and Bain, and from the October 1932 number of the *American Journal of Roentgenology*.]

EXPERIENCE WITH RUSSELL'S VIPER VENOM

By J. B. HANCE, O.B.E., M.A., M.D. (Cantab.), F.R.C.S.E.
LIEUTENANT-COLONEL, I.M.S.

Bangalore

Case 1.—The operation of tonsillectomy was performed on a male aged 48, Anglo-Indian, for the removal of grossly infected tonsils. This patient had warned the writer beforehand that he was, what he termed, a 'bleeder', and in consequence his coagulation time had been estimated and was found to be 6 minutes. In view of this increased figure, previous medication by calcium had been undertaken and prophylactic hæmoplastin had been administered.

In spite of these precautions the patient bled freely from the tonsillar site, the blood being notably fluid and with little tendency to clot. The hæmorrhage was of the general oozing type, there being no particular bleeding point. Since neither continued pressure nor suture of the pillars succeeded in stopping this bleeding, small pledgets of sterile cotton-wool were soaked in 1 in 10,000 solution of Russell's viper venom and these were swabbed over the tonsillar site. The effect was immediate and dramatic. The bleeding stopped forthwith, and the pillars of the fauces were sutured without trouble over a dry tonsillar bed. Beyond one vomit of blood which had obviously been swallowed, no further hæmorrhage took place.

Case 2.—Female, aged 36, Anglo-Indian. This patient had had 17 children and was reported to have bled after all her confinements. The last five of her confinements had taken place in the Lady Curzon Hospital, Bangalore, and on each occasion the patient had had postpartum hæmorrhage with or without retention of the placenta. After the 17th confinement, sterilization was recommended; but the husband of the patient was at that time unwilling. Subsequent to her discharge from hospital, she had, however, suffered from menorrhagia with severe floodings and passage of clots and for this complaint she again sought advice.

On examination, the uterus was found to be enlarged and the hæmorrhage was considered to be metropathic in origin; and hysterectomy was recommended.

On the 14th November, 1936, under spinal percaïn anæsthesia, a total hysterectomy was performed without any undue operative difficulty, and the patient returned to the ward in good condition. Five hours later, the writer was sent for by the house surgeon urgently on account of copious hæmorrhage. On arrival he found the patient collapsed with a pulse of 160 and barely perceptible, respirations were sighing, and the patient was blanched in a cold clammy sweat.

Immediate operation was performed, the wound opened up and a sub-peritoneal hæmatoma of the pelvic cellular tissue of the size of approximately a foetal head was evacuated. It was then found that the hæmorrhage was of the general oozing variety and that beyond two small para-vaginal veins there were no bleeding points; and the previous ligatures were verified. Ligature of the two para-vaginal veins did not materially lessen the hæmorrhage.

Accordingly, with the morning's experience of Russell's viper venom fresh in his mind, the writer decided to take the risk of an intravenous injection of a minute dose of Russell's viper venom. The patient's condition was desperate and there was no doubt that death would ensue rapidly unless the hæmorrhage could be controlled. The 1 in 10,000 solution of the morning was again diluted with sterile double-distilled water 1 in 10 making a final strength of 1 in 100,000. Of this solution 0.5 c.cm. was injected into the vein and the effect on the pelvic cellular oozing noted. Since in 10 minutes no marked effect had been produced the injection was repeated. It then became apparent that the cellular tissue was visibly drying and the oozing was visibly lessening. Thereupon a vaginal drain was inserted and the pelvic peritoneum united and the wound was closed in layers in the ordinary way.

Immediate direct arm-to-arm transfusion of 500 c.cm. of blood was carried out on the operation table; and the patient left the table with a pulse of 140, a better colour and generally in better condition than when she was brought to the theatre. There was no further evidence of hæmorrhage and the patient's condition progressively improved. During the 48 hours after operation the loss per vaginam was less than the normal menstrual loss of a healthy woman.

The preparation of Russell's viper venom used in these cases was 'Stypven' made by Messrs. Burroughs Wellcome and Co., a sample of which had, most fortunately, kindly been left by their representative, Mr. A. C. Johnston. It should here be stated that the preparation as issued by Messrs. Burroughs Wellcome most definitely states that it is 'not for injection'. But in conversation with Mr. Johnston the latter observed that he had heard rumours that successful results had been obtained elsewhere by the intravenous injection of a preparation of fresh Russell's viper venom in a dilution of 1 in 100,000. On subsequent enquiry, however, it turned out that this dilution is injected intradermally and not intravenously in the institution concerned. In view of the desperate condition of the patient, and the morning's experience, the writer decided that the risk was justifiable, and the results are here recorded.

Case 3.—Capt. T., aged 68, European, was admitted into the Bowring Civil Hospital on the 27th October, 1936, suffering from rigors, biliary colic and jaundice. He gave a history

of having bled freely all his life from slight injuries. Accordingly, his coagulation time was estimated on the 28th October and was found to be 9 minutes 20 seconds. His jaundice cleared up under medical treatment, but two subsequent severe attacks of biliary colic dictated operation. Accordingly, intensive calcium therapy was instituted and by the 15th November the coagulation time had been reduced to 6 minutes 30 seconds. Lower than 6 minutes it could not be brought with calcium and hæmoplastin.

The operation took place on the 20th November, the coagulation time that morning being 6 minutes. Half an hour before operation 0.5 c.cm. of 1 in 100,000 solution of Russell's viper venom was injected intradermally and the coagulation was estimated on the operating table before commencement. By then it had fallen to (complete coagulation) 4 minutes 30 seconds. The operation was commenced and the gall-bladder was found to be full of gall-stones, the cystic duct dilated and the common bile duct to be similarly filled with stones. The gall-bladder and 234 bile stones were removed, the common bile duct was drained, and the patient returned to bed.

During most of the operation, which was not without difficulty and took 75 minutes, there was no noticeable oozing in spite of the fact that several filmy adhesions, partially organized, had to be separated. In the final stages, however, when the abdomen was being closed, a certain amount of rather fluid oozing was noticed along the drainage tube left in Morrison's pouch. The coagulation time was accordingly estimated after the patient returned to bed, when it had risen to 5 minutes 45 seconds. A second 0.5 c.cm. intradermal injection of Russell's viper venom 1 in 100,000 was therefore given. Four hours later the coagulation was 5 minutes 30 seconds. In the evening, 8 hours after the second injection, the coagulation time had risen to 6 minutes; and, the next morning, 24 hours after the operation, the same value was obtained. After the second injection of Russell's viper venom all visible oozing along the tube completely stopped and did not recur.

Discussion

These three cases illustrate the use of Russell's viper venom as a styptic in three different ways. In the first case the preparation was used as the makers recommended after research on laboratory animals, and was a notable success. In the second case, the venom was used in a method which, so far as the writer is aware, has not been previously employed. The need was desperate and heroic measures were justifiable, and, in the event, justified.

In the light of the events here recorded it now seems probable that the assumption that both the postpartum hæmorrhage and the

menorrhagia were metropathic in origin is, at least partially, incorrect. The patient is an Anglo-Indian woman in poor circumstances, and her tendency to hæmorrhage of the oozing type is, in the writer's opinion, more probably attributable to persistent malnutrition, and also to an imbalance in her diet. In consequence, the blood calcium was probably low and the vitamins, notably 'A' and 'C', were almost certainly deficient. While the writer would hesitate to repeat the intravenous injection of the venom except in grave emergencies, or in the control of bleeding where he had reason to suppose that the blood coagulation time was abnormal, he would have no hesitation whatever in repeating it in similar circumstances.

In the third case, so far as the writer is aware, the intradermal method has not previously been used as a prophylactic, although the intradermal injection of Russell's viper venom in cases of typhoid fever with hæmorrhage has, the writer believes, been used as a curative measure with conspicuous success in Mysore. This case is, in the writer's opinion, the most satisfactory and convincing of the three, in that it was possible to check the effect of the administration of the venom by the estimation of the coagulation time of the blood. The case would, therefore, appear to indicate that the intradermal injection of the Russell's viper venom does, in fact, lessen the coagulation time in patients where the latter is naturally high.

The writer is aware of the danger of deductions from isolated cases; but he does consider that these cases, especially the second and the third, are sufficiently impressive to justify their being placed on record, in the hope that such apparently dramatic results may be confirmed by other observers. Should they be so confirmed, venom therapy would appear to open up a wide new vista in the treatment of hæmorrhage. Hæmoptysis, hæmatemesis, hæmorrhage from duodenal and typhoid ulcers and, notably, military surgery are merely some of the obvious fields of employment of this remedy.

The writer is indebted to the courtesy of Dr. T. Seshachalam of Mysore for the details of intradermal technique, as employed in the Krishnarajendra Hospital there, kindly supplied after the operation on the second case. He further wishes to record his acknowledgments to Messrs. Burroughs Wellcome and Co., and to their representative, Mr. A. C. Johnston, for the supply of the sample of their preparation 'Stypven'.

Summary

(1) Three cases are recorded in which Russell's viper venom was used in the control of bleeding, the preparation being used differently in each case :

- (a) by direct application,
- (b) by intravenous injection, and

(Continued at foot of next page)

THE MORTALITY OF OPERATIONS FOR VESICAL CALCULUS IN INDIA

By E. W. HAYWARD, F.R.C.S.E.

Principal Medical Officer, Jodhpur State

THE following is an analysis of 359 consecutive operations done by various surgeons in the Windham Hospital, Jodhpur, during the years 1933-35. The only cases excluded are those few who had small stones removed under local anaesthesia with cystoscopic rongeur forceps and one who also had a stone in the kidney which was successfully removed at the same operation as litholapaxy was performed and which has been classified under stone in the kidney. At the end, the records of 78 cases done in the first eight months of 1936 are partially analysed with those of the last half of 1935.

Previously published figures

Rowlands and Turner quote various mortality rates, the most recent being that of the Mayo Clinic which records 153 litholapaxies and 395 suprapubic lithotomies with death rates of 1.3 and 8.6 per cent, respectively. These figures presumably refer to well-fed Americans, whereas Sir Peter Fryer's figures consist chiefly of Indian ryots—a very different proposition. In my opinion Sir Peter's record of 986 litholapaxies and 116 suprapublics with death rates of 2.53 and 14.65 per cent is not likely to be improved upon to any great extent in India until the patients come for treatment before such health as is naturally theirs is weakened by months and years of pain and pyuria accompanied by the semi-starvation that is the lot of most who are no longer able during the monsoon weeks to till the field on whose produce they live from year to year. Better instruments and anaesthetics may help, but I am convinced that real improvement is impossible until the patients come so early that a stone of golf-ball size will fascinate those of us who to-day are scarcely interested in anything smaller than a cricket ball. Winsbury White quotes Anthony's wonderful results, but in the absence of details I am not prepared to comment on his 1,532 litholapaxies but only 56 lithotomies with death rates of 0.6 and 14.3 per cent, respectively.

The anaesthetic

Gas and oxygen were not used on any of the cases under reference. It was not at first available and even now has to be used very sparingly as each empty gas cylinder has to travel over

(Continued from previous page)

(c) by intradermal injection.

(2) In view of the dramatic results obtained and the obvious wide field of employment for Russell's viper venom, if established, it is hoped that the cases here recorded will induce other observers to confirm the writer's results.

2,000 miles before it returns duly refilled. The normal anaesthetic used has been A. C. E. followed by ether given through a Shipway's apparatus. Spinal anaesthesia with either novocain, pantocain or Barker's stovaine has been used in some cases but often this was prevented by the patient having a very low blood pressure. Cases with chronic bronchitis were usually done under local novocain but, with this, wounds often tended to become septic and heal slowly, though this was due to the novocaine or to the patient's condition cannot be said. One or two litholapaxies were done with a local urethral anaesthetic, but this asks a good deal of the patient, however gentle one is.

Pre-operative treatment

The routine in stone cases starts with a sounding in the out-patient department. This may appear to be an out-of-date method, but with a thousand outpatients a day and a limited staff it is the quickest and cheapest, as the repair of a damaged sound that the patient has hurled on the floor costs less than the repair of a cystoscope that has gone the same way. I must add, however, that doubtful cases are subjected to both cystoscopy and radiography. After a day or two in bed, during which time the ectoparasites that usually accompany the patients are caught, nails and hair are cut and bodies washed (often for the first time ever with soap as well as water), the patient is taken to the theatre. A cystoscopy is now always done except in the case of females and boys about ten years of age. Litholapaxy is regarded as the operation of choice and is always done when not contra-indicated. If contra-indicated suprapubic lithotomy is done.

Contra-indications to litholapaxy

I regard the following as the main contra-indications:—

1. General weakness of the patient making a long operation inadvisable. This is largely a matter of the size of the stone although the capability of the surgeon to perform a speedy crushing also counts. This is by far the most important contra-indication to litholapaxy and is the one that chiefly accounts for the large number of suprapubic lithotomies done and their much higher mortality.

2. Too small a urethra to permit the passage of a lithotrite of the size needed to crush the particular stone present. Above five years the age of the patient is almost immaterial as a small lithotrite can always be passed; it is the size of the stone that matters.

3. Stones impacted in the neck of the bladder.

4. Stones which are very large or very hard—we have not met any that are too soft or too small or formed round foreign bodies.

5. The presence of a diverticulum of the bladder or a much enlarged prostate.

6. Advanced cystitis with a contracted bladder.

7. Urethritis, undilatable urethral stricture and a small fibrotic bladder must also be remembered as rare contra-indications.

I do not regard a small papilloma or other new growth as a contra-indication to litholapaxy as it should be possible to tilt the table and keep the stone away from it; later on it can be treated by diathermy, thus avoiding a cutting operation, which is both distasteful to the patient and risky as to implantation.

Other operative methods

I have no experience of perineal litholapaxy or lithotomy, or of vaginal lithotomy, except that I have had to transplant the ureters in a man who had had most of his bladder and perineum destroyed by an enthusiastic perineal litholapaxist elsewhere.

Operative details

It does not seem necessary to go into these, except to say that the clean and unbruised

either by flushing with a Bigelow evacuator or through an operating cystoscope. Similarly any loose piece of mucous membrane must be removed and not left to form the nucleus of a second stone. Cystoscopy a week after litholapaxy also gives one an excellent idea of what damage has been done to the bladder—it is very seldom (except in the case of really small stones) that one does not see one or two areas of submucous hæmorrhage, and, with an inexperienced operator, the appearance reminds one of a case of confluent smallpox. I am sure that this delay before doing the final cystoscopy is more than justified by the negligible recurrence rate that it ensures. We can only remember one case coming back in the last five or six years, but unfortunately we have no accurate records on this point nor are follow-up clinics possible.

The mortality at different ages

This is clearly shown in the following table and no comment is needed:—

Age	Lithotomies	Died	Percentage mortality	Litholapaxies	Died	Percentage mortality	Total operations	Died	Percentage mortality
1 to 7 years.	139	6	4.3	27	0	nil	166	6	3.6
8 to 15 years.	36	2	5.5	6	0	nil	42	2	4.7
16 to 40 years.	21	3	14.2	53	1	1.8	74	4	5.4
41 to 60 years.	29	12	41.3	44	2	4.5	73	14	19.1
61 and over.	2	2	100	2	0	nil	4	2	50
	227	25	11	132	3	2.2	359	28	7.7

bladder can usually be completely sutured after suprapubic lithotomy, a catheter being tied in per urethram and a rubber dam placed in the cave of Retzius. Septic bladders and those that have suffered much trauma during the withdrawal of the stone are best drained. Primary closing reduces the stay in hospital from an average of about 30 to 16 days. It must be remembered, however, that these long averages are largely due to the feeble old men who linger for weeks and will not heal up completely, but who cannot be discharged to their mud huts, perhaps fifty or more miles across the sandy desert from the nearest railway station, until they are fully healed and fit to face this journey, often on foot, at best on a camel or bullock cart.

Litholapaxy cases can be discharged after two or three days. I much prefer to keep them in for seven days at the end of which time they are cystoscoped. By this time all fragments of stone left behind at operation that are going to pass out per urethram have gone and if any piece is left, however small, it must be removed

N.B.—These figures correspond closely with those for the previous four years which were 207 lithotomies with 22 deaths, a rate of 11 per cent, and 204 litholapaxies with 5 deaths, a rate of 2.5 per cent.

The causes of death

1. Age group 1 to 7 years.
 - (a) Heat exhaustion and hyperpyrexia on the first day.
 - (b) Asthenia with pneumonia. He had been classed as a bad risk before operation and died on the 12th day.
 - (c) Entero-colitis 20th day, cause unknown.
 - (d) Cerebral malaria 11th day, despite being quite well until the 10th day and receiving quinine.
 - (e) Diarrhoea and fever 2nd day. Cause unknown.
 - (f) Vomiting and diarrhoea of unknown origin beginning on the 11th day, till when the child had been quite well, and ending fatally on the 14th day.

2. *Age groups 8 to 15 years.*

- (a) Asthenia with râles in the lungs (a very feeble patient).
 (b) Another weak patient developed basal congestion, then pneumonia and died on the 11th day.

3. *Age group 16 to 40 years.*

- (a) Rupture of the bladder during litholapaxy accounts for one death.
 (b) Asthenia claimed two patients who faded away one and two months respectively after operation.
 (c) After spinal stovaine one man had a steadily falling blood pressure and respiratory embarrassment and died on the 3rd day.

4. *Age group 41 to 60 years.*

- (a) Asthenia claimed four suprapubic victims who just faded away on the 5th, 13th, 20th and 120th days after operation and one litholapaxy case on the 7th day.
 (b) Post-operative pneumonia accounts for four who died on the 2nd, 3rd, 7th and 17th days.
 (c) One died from toxæmia on the 9th day, the bladder having been grossly septic at the time of operation.
 (d) One died from heart failure on the 9th day, autopsy revealing advanced myocardial degeneration.
 (e) One case was lost on the 3rd day, due to rupture of the bladder during litholapaxy.
 (f) One collapsed and died very rapidly for no apparent reason on the 5th day after the removal of a stone and a diverticulum.

was noticed. No really big stones were removed in this series; the largest only weighed 7 ounces 5 drachms when dry.

The mortality at different seasons

By the middle of 1935 we had realized that cases did much better in the cold weather than in the hot. Between June 1935 and August 1936, 136 cases were operated on, of which those done in 1935 are included in the three-year records given above, but those of 1936 are now analysed for the first time.

Of nine cases that died out of the 136 operated on, none died between 1st October and 30th April. The worst months here climatically are May to September when the thermometer may reach 123°F. in the shade and just before the rains break in July the humidity also is very high. There were no selection of cases, they came fairly regularly all the year round, with however some increase during the hot weather when they do not work in their fields. Fans are of course provided in the wards but they only stir up the hot air and do not really cool the patient down. The operating theatres are air-conditioned.

The mortality at different concentrations of blood urea

Similarly by the middle of 1935, a connection had been noticed between raised blood ureas and the operative prognosis. Of the 136 cases operated on since then, 59 did not have their blood urea taken as 52 of them were children under 16 years and seven of them had to be operated on soon after admission owing to a certain degree of retention of urine. The urine urea was not done in any case. The 77 cases whose blood ureas were examined resulted as follows:

Blood urea	Lithotomies	Died	Percentage mortality	Litholapaxies	Died	Percentage mortality	Total operations	Died	Percentage mortality
(a) 25 to 50	16	3	19	52	1	2	68	4	6
(b) 50 to 60	2	1	50	1	1	100	3	2	66
(c) Over 60	2	1	50	4	0	nil	6	1	17

- (g) Diarrhoea, possibly dysenteric, claimed one victim on the 14th day.

Of these all had a pre-operative note stating that their general health was poor or very poor except (e), (f) and (g).

5. *Age group 61 and over.*

- (a) One feeble old man of, he said, 95 survived for 11 days and then died of pneumonia, the anæsthetic having been local novocain.
 (b) Another feeble one died of exhaustion on the 21st day.

The mortality of different types of stones

No relationship between the chemical composition or the sizes of stones and the death rate

From this, the mortality of those with blood ureas under 50 mgm. is seen to be 6 per cent while of those over 50 it is 33 per cent.

The causes of death

In the two young children out of the 59 cases whose blood urea was not done, the cause of death was heat stroke in one, coming on ten hours after the operation with a rapid rise of temperature and convulsions, and in the other diarrhoea and vomiting which began on the 11th day, ending fatally within 48 hours.

The causes in the cases whose blood ureas are recorded in the groups above were:—

Suprapubic lithotomies.

(a) 1. Collapsed on 5th day and died for no apparent reason [see 4. Age group 41-60, (f)].

2. Faded away 5th day after spinal anæsthetic and slight accumulation of fluid in cave of Retzius which did not drain well along the rubber dam.

3. Very septic bladder. Was given ACE, followed by open ether. Died apparently from chloroform poisoning on the 4th day.

(b) Very poor subject. Local novocain anæsthesia. Died on the 3rd night of myocardial failure.

(c) Poor subject, slightly insane. Local novocain anæsthesia. Recovered enough to go in a wheeled chair by 15th day, then faded away and died on the 29th day.

Litholapaxies.

(a) Rupture of bladder [see 3. Age group 16-40 (a)].

(b) Fell down dead while walking back from the latrine the day after operation. No post-mortem.

Summary

The prognosis of operations for vesical calculus appears to become progressively less favourable as the age of the patient increases. A blood urea of over 50 also reduces his chance of survival to 67 per cent as compared to 94 per cent if it is under 50 mgm. During one cold weather no deaths occurred but they started again as soon as the next hot weather arrived. Climatic conditions therefore appear to have some effect.

The 11 per cent mortality of suprapubic lithotomy is so much higher than the 2.2 per cent of litholapaxy because the latter is the operation of choice, while the former is done on those cases who are unfit for a long, general or a spinal anæsthetic or who have very large stones or septic bladders and are obviously bad risks from the very beginning. Little if anything can be done to reduce this mortality under the present conditions of life of the patients, whose poverty, physique and ignorance has to be seen to be believed. The risk of litholapaxy is very slight (1 in 132) apart from the surgical error of rupturing the bladder (2 in 132), a tragedy which has occurred less frequently as the various operators have become more experienced, although attempting to crush a relatively big stone in a small bladder may lead to this tragedy even in the best hands.

In conclusion, a stone case who is physically fit and young would appear in a good climate to have an excellent prognosis, but the feeble old man with a high blood urea in the middle of the hot weather is a very grave surgical risk.

The prognosis of these cases seems to depend really on the ability of the system to withstand the shock even of a rapid (6-12 minutes)

(Continued at foot of next column)

DEEDS OF VIOLENCE IN INDIA IN 1935-36 AND OTHER CRIMES IN WHICH SEROLOGY PLAYS A PART

By S. D. S. GREVAL, B.Sc. (Punjab), M.D., Ch.B.,
D.P.H. (Liverpool)

MAJOR, I.M.S.

Imperial Serologist and Chemical Examiner to the
Government of India, Calcutta School of Tropical
Medicine

It occurred to me that a little amplification of one of the tabular statements prepared for the annual report on the working of this department would make the figures given therein useful to the ethnologist, the economist and the statistician. This has been done. Purports have been added to the enactments.

The department is connected with the deeds of violence thus: Chemical examiners in the provinces receive all the suspected materials, they forward to the department all exhibits on which they find blood; but as often as not they also forward exhibits on which they have not found blood, with the remarks 'Blood not confirmed'. The department undertakes to determine the origin of the blood, human or animal. Material other than blood is also received and its origin determined serologically, e.g., semen, flesh, bone, etc.

The table gives only the enactments under which enquiries were being made against an alleged wrong-doer at the time the suspected material was collected. This fact would account for the frequent interchange of the allied sections of the Indian Penal Code. Multiple enactments or enquiries under sections dealing with comparatively trivial failings of human conduct are legal manoeuvres.

The table does not give (1) the exact total of all crimes of violence, (2) convictions or even (3) cases found positive for the evidence sought for. It is on the whole, however, a good indicator of crimes committed in the country.

(Continued from previous column)

suprapubic lithotomy under local novocain. The straw that breaks the camel's back may be the heat of the ward, the general weakness of the patient or a certain degree of renal inefficiency, but nearer than that I have been unable to get in considering the causes of death after operations for vesical calculus.

Those who have worked among the ryots of India will not enquire why the more unfavourable cases are not postponed till they are fit and the weather cool. To those who have not worked here, I would say come and see the physique and mentality of these people before being too critical of our operative mortality.

Finally I must record my gratitude to my colleagues, Dr. B. L. Mehta and Dr. J. S. Mathur, for their great help in the preparation of this note.

A table showing the number of cases of crime in India, by provinces, under various enactments, tested by the Imperial Serologist and Chemical Examiner to the Government of India, Calcutta, in 1935-36.

The following extract from a case, apart from the intrinsic interest it has as an account of a human sacrifice, will show how a negative serological finding may be compatible with conviction :—

Sessions case No. 49 of 1936

Salem Division, Madras

Prisoner—Chinna Chetti *alias* Munippan.

Offence—Section 302, I. P. C.—murder.

'On the night of the 31st December, 1935, he intentionally killed his son, Hanumadu.

The deceased, a suckling babe at the time of his death, was the youngest of his three children by his wife (P. W. 7), who lived with him at Bennangur about 25 yards from the Karaga Mariamman Temple. About three weeks before the occurrence, he proposed to her the sacrifice of one of their children to the Mariamman goddess, as an effective method of getting access to hidden treasure buried in a forest and becoming wealthy; but she did not take him seriously. After taking his supper with toddy and fowl curry at about 10 p.m. on the day of occurrence, he left the house saying that he had to go to the village, and, returning about a quarter of an hour later, went to bed. Some time after this, as she was just getting sleep, she saw him stand for a while near the bamboo cradle where the deceased slept, and abruptly go out of the house closing the door behind him. When she woke up shortly afterwards to suckle the child, she found it missing from the cradle. Thereupon she came out, and, seeing light at that untimely hour in the temple, ran there, when to her great horror she saw her husband place the severed head of the child in a mud bowl, used as a lid for a mud pot, containing two karagams (sacred pots) secured in a pit which served as an altar in front of the idol. He next covered the bowl with a granite slab. P. W. 7. set up a yell at this ghastly sight, but the accused encouragingly asked her not to cry saying that the goddess will perform a miracle and restore the child; and pushing her away carried the trunk of the infant towards the burial ground about a furlong away.....

..... In the lower court, P. W. 7 posing as an eye-witness deposed that she found her husband put his foot on the child's chest and sever its head from the trunk with M. O. 1, their bill-hook. But neither here nor before the village headman did she claim to have actually witnessed the deed. It is not unlikely that when P. W. 15 noticing some stains on her sari (certified by the chemical examiner not to be of blood) questioned her about them, she developed the story of having been an eye-witness to the commission of the crime by her husband and produced M. O. 1 in proof of her assertion. The Imperial Serologist could discover only the blood of a bird (probably a fowl) on this weapon..... These circumstances seem to suggest that P. W. 7 was at first probably a consenting party to the child's sacrifice and possibly believed that such an act of apparent religious merit might even redeem its life. So grotesquely superstitious and credulous are some of the village folk..... One fact emerges from her inconsistent statements, namely, that she cannot be trusted in all that she says..... The accused's plea of alibi stands unproved, and I find not the slightest reason for disbelieving the neighbours who saw him that night in his house and were told by him that P. W. 7 was weeping for nothing.....

The assessors' unanimous opinion that the accused is not guilty is based solely on the untrustworthiness of P. W. 7's testimony..... Disagreeing therefore from the assessors, I find him guilty as charged. Only one sentence is possible..... till he is dead'.

The bill-hook, evidently, figured in the fowl curry and not in the decapitation of the infant.

A CASE OF HÆMOGLOBINURIA CAUSED BY PLASMOCHIN TAKEN AS A PRO-PHYLACTIC AGAINST MALARIA

By MIN SEIN, M.B. (Cal.), M.R.C.P. (Lond.)

CAPTAIN, I.M.S.

Civil Surgeon, Toungoo, Burma

As far as I could make out from limited references no case has been recorded in which plasmochin, taken as a prophylactic against malaria, has resulted in hæmoglobinuria. The interest in the following case lies in the fact that hæmoglobinuria could be definitely attributable to the taking of plasmochin.

The patient, an Indian sepoy (J. S.), aged 20 years, was one of the party of men from the 1/17th Dogra Regiment engaged on a flag march in the jungle in Tharrawaddy district in Lower Burma, between the 31st October and 5th November, 1932. Each man was being given 0.04 gramme plasmochin daily as a prophylactic against malaria. After the end of the fourth day's march (*i.e.*, on 3rd November), he reported sick and was transferred to Mingaladon by train. His complaints then were being feverish, general abdominal discomfort and pain without nausea or vomiting. He was admitted into the British Military Hospital (I. W.), Mingaladon, on 5th November for the following complaints:—

Pain in the left upper quadrant of the abdomen, and fever. The pain was mild and temperature was 99.5°F. in the morning and 100°F. in the evening. There was no previous history of malaria. Physical examination was negative. There was no superficial nor deep tenderness. Spleen was not enlarged. No malarial parasites were found in the blood smear. Next morning he was reported to have had a 'fainting fit'. The sub-assistant surgeon who saw him first found him in a state of shock with cold extremities, covered with sweat. The pulse was weak and thready. He recovered soon after and was treated for collapse. I saw him a little while later when he complained of pain in the left loin. The patient explained that he had an acute attack of abdominal pain limited to the left side which was so severe that it doubled him up and that he had lost consciousness.

The patient was found to be markedly jaundiced and in a state of collapse with cold and cyanosed extremities. Temperature was normal; pulse was soft but regular and of normal rate. Hæmic murmur was heard in the pulmonary area. Pain was complained of just below the last rib on the left side on bimanual pressure and on deep inspiration. The kidneys were not palpable. There was slight œdema of the feet.

The patient could not pass urine when asked to do so. Close questioning elicited the fact that the patient had passed dark-coloured urine since the 3rd November, but had not reported this as he has taken no notice of this fact. Treatment was instituted with warmth, and massive doses of alkaline diuretics. At about noon the patient passed about 10 ounces of urine which was port wine in colour. The urine contained bile, blood pigment and albumin. Microscopic examination revealed few red blood cells, and epithelial cells. Glucose and sodium bicarbonate, barley water and soda water were given *ad lib*. There were no malarial parasites in the blood smear.

Subsequent progress:—

There was fever for a few days. Jaundice became very marked and generalized on the next day and the patient complained of giddiness. General condition was fair. Malarial parasites were not found in the blood smears taken on several occasions. The red blood cell count was $3\frac{1}{2}$ millions, and the leucocyte count 7,500 per c.mm. Hæmoglobin was 45 per cent. Urine was still port wine in colour and contained bile, blood pigment, albumin, and a few red blood cells. The total

quantity passed during 24 hours was 60 ounces. Differential count showed polymorphonuclears 67 per cent, lymphocytes 25 per cent, large mononuclears 7 per cent and eosinophiles 1 per cent. Large doses of ferri et ammonii citras were given with a little arsenic.

The condition gradually improved day by day and by the 15th November the jaundice had cleared up, but anemia was still marked. The pain and tenderness in the loin disappeared in a few days. The patient was discharged cured on the 30th November when red blood cells were $4\frac{1}{2}$ millions and leucocytes were 7,600 per c.mm. and hæmoglobin 85 per cent.

The following examinations were also done:—Blood and urine culture—negative. Van den Bergh's test—direct reaction was negative and indirect reaction was positive. The patient was examined regularly afterwards but recovery was complete and maintained.

Comment

In spite of widespread interest maintained, the cause of hæmoglobinuria (blackwater fever) has never been satisfactorily determined. Cases have been published where the onset of hæmoglobinuria had occurred under the following conditions:—

(1) Independently in a recognized malarial subject.

(2) During an attack of malarial fever—

(a) when quinine had not been given,

(b) when the patient had been treated with quinine alone or in combination with other drugs, and

(c) when atabrin and plasmochin had been given.

Several authorities are agreed that quinine may start an attack of hæmoglobinuria (blackwater fever). Similarly, cases have been published in which treatment of malaria with plasmochin, with or without atabrin, had resulted in hæmoglobinuria. But there seems to have been no record of hæmoglobinuria occurring as a result of taking plasmochin as a prophylactic, though it has been used extensively for this purpose. During the Burma Rebellion (1930–32) plasmochin was used extensively, side by side with quinine, as a prophylactic against malaria. In the Pegu area where I was in medical charge of the troops, about 300 men received a daily dose of 0.02 gramme plasmochin during November and December 1931. The minimum period of administration was three weeks and the maximum seven weeks. A careful watch was kept for any untoward symptoms but in all there were not more than half a dozen cases in which the symptoms complained of were mild epigastric pain or colic, easily controlled by stopping the administration of the drug and giving gastric sedatives. This is in conformity with the experience of others who have used the drug for a similar purpose. But the case described demonstrated that such a small dose as the total amount given in four days, *i.e.*, 0.16 gramme, could, in susceptible subjects, result in hæmoglobinuria. In this case, either due to defective excretion, to idiosyncrasy, or to both, the drug caused a massive and

THE DENUDED PENIS AFTER OPERATION FOR ELEPHANTOID SCROTUM

By M. M. CRUICKSHANK

LIEUTENANT-COLONEL, I.M.S.

General Hospital, Madras

THE treatment of the penis entirely denuded of skin after operative treatment for elephantoid conditions of the penis and scrotum has never proved satisfactory. Several lines of treatment have been advised.

The application of a Thiersch graft, the usual procedure, results in a penis which is simply tucked down to the pubic region by a tight collar of fibrous tissue, the stretched penis, upon which the grafts have been laid, collapsing inside the bandage, the moment tension ceases, the grafts merely tucking up round its base.

Connell (1932) states that Thiersch's method appears to be unsuitable and that he personally has never used it. His method of dealing with the raw penis is by threading it through a subcutaneous tunnel on the inner aspect of the thigh and liberating it some ten days later by means of a simple flap incision.

This flap, which must be broad when dissected up, gives the penis an abnormally bulky covering of skin and subcutaneous tissue. The result however is not always a happy one, because, unless broad, the flap may become gangrenous, may not fit round the penis without a certain amount of tension, and, as a result, a considerable amount of scar tissue forms on

(Continued from previous column)

sudden hæmolysis with the resulting hæmoglobinuria. From this it may be deduced that in blackwater fever also the toxins of the malarial parasites by themselves or with the help of drugs such as quinine, atabrin or plasmochin might cause massive hæmolysis, hæmoglobinæmia and hæmoglobinuria in susceptible individuals.

I have to thank the Officer Commanding the British Military Hospital (I. W.), Mingaladon, for permission to publish the above case which was under my charge whilst I was a medical officer attached to that hospital.

[Note.—The writer has used synonymously hæmoglobinuria, a symptom, and blackwater fever, a clinical syndrome; this is not in our opinion justifiable.

He refers to the frequent use of plasmochin as a prophylactic in malaria. We are doubtful if it was ever used very extensively as a personal prophylactic, as early in 1931 a crucial experiment was performed in which it was shown that a total dose of 0.42 gramme of plasmochin given over a period of a week did not give protection against malarial infection. Such a dose may be expected to cause symptoms in quite a large percentage of the people taking it.

The value of plasmochin lies in its anti-gametocyte powers. A total dose of 0.06 gramme is usually sufficient to clear the blood of gametocytes; in this capacity it is valuable as a general prophylactic measure.—EDITOR, I. M. G.]

the penis which tends to vitiate results which at the best cannot be termed æsthetic.

In an endeavour to avoid death of parts of the flap, I have dissected up and clothed the penis, short sections at a time. The ultimate

result is no better, because the organ, due to the vagaries of fibrosis, is misshapen and requires several plastic operations to render it more or less straight and central.

Again, I have tried making use of a pedicle graft from the thigh with which to clothe the penis. The results are about the same as those obtained by the 'tunnel' operation.

Such disheartening results might, I thought, be obviated could the penis but be kept extended for a time sufficient to allow pedicle flaps or Thiersch grafts to 'take'.

With this object in view I had made a splint on the lines of a Cabot splint, with bands encircling the thighs, by means of which it could be fixed in one position, these bands lying in the groin along Poupart's ligament, so that even if the patient pulled his knees up in bed yet the apex of the splint remained approximately in the same position. The penis is extended by means of a silk suture passed deeply through the region of the frænum and

RHEUMATIC FEVER IN THE PUNJAB

By B. L. KAMRA, M.B., B.S.

Medical Officer in charge, Rattewala (Sohangarh) Dispensary, Tehsil Muktsar, District Ferozepore

EVIDENCE in support of the existence of rheumatic fever in the Punjab has been presented by Hughes and Yusuf and Wig. The purpose of this article is to support the view of the above workers, and to attempt to gauge the frequency of the disease in this rural area of the Punjab.

Out of the new patients under 30 years of age, attending the outdoor department of this dispensary during the period extending from 12th August, 1935, to 19th November, 1935, as

(Continued from previous column)

tied to the small cross bar at the apex of the splint.

So positioned, movements of the thighs are not transmitted to the splint in any degree sufficient to pull out the extending suture. Long Thiersch grafts are now cut from the thigh—one or two will suffice—and applied like a roller bandage to the penis from the corona to the base, care being taken to see that at the base the graft is made to lie snugly under the thick pubic skin.

At points along its course the graft is tucked down at its edge by fine catgut sutures. This prevents any movement on the part of the graft, which is simply covered with a piece of gauze soaked in sterile liquid paraffin applied as a small roller bandage. I have tried applying the grafts vertically along the penis but better results have followed in those cases where the graft or grafts have been applied as one would a roller bandage. The post-operative result, both from cosmetic and utilitarian view-points, is far superior to that obtained by the methods mentioned above where no splint is used. That some shrinkage of these grafts will take place cannot be denied, but, judging from results a month after operation, I feel sure that the final result will be very satisfactory.

It now remains to be seen, whether or not, using this splint, better results will follow the use of a Thiersch graft or a full thickness pedicle graft.

The splint has been made for me by Messrs. Hebbar Brothers Ltd., 246, Thambu Chetty Street, Madras.

To Dr. Hebbar I am much indebted for the help he has afforded me in making various models of the splint.

REFERENCE

Connell, W. K. (1932). Operative Treatment of Elephantoid Scrotum. *Brit. Journ. Surg.*, Vol. XIX, p. 651.

many as could conveniently be done were daily examined for valvular lesions and an attempt was made to elicit choreic movements, if present, by asking them to spread out their hands with palms downwards. On meeting with positive signs, careful enquiry regarding past history of rheumatic infection was recorded. Twenty patients were examined daily and the total number thus examined was 1,000. The findings are tabulated below :—

The total population of these villages is 5,625 and the number of persons seen by the writer during the last 12 months that are known to have suffered from rheumatic fever with or without consequent endocarditis were 12, that is, 2.13 per thousand of the total population.

During the period extending from 1st January, 1933, to 30th September, 1935, 247 cases were treated in the indoor department of this dispensary for different diseases. Out of these, four

TABLE

Abstract of the examination of 1,000 cases (outdoor) for rheumatic infection

TOTAL ..	992	1	1	2	4	1,000

In the course of this search for valvular lesions, which on account of the rush of work in the 'outdoor' could only be done by auscultation, both systolic and diastolic murmurs in the mitral area and systolic murmurs in the pulmonary were met with. The latter was always disregarded and not accepted as evidence of rheumatic infection; they were found to be hæmic murmurs in all cases. The mitral systolic bruit was found in cases of prolonged pyrexia and anæmia; it was due to the atony of the myocardium and the consequent dilatation of the mitral ring. It always disappeared soon after the removal of the cause. Mitral systolic murmur, therefore, was not taken as evidence of rheumatic infection, unless there was a definite history of acute or sub-acute articular rheumatism or chorea.

The sound in the mitral area normally varied so much in character in different cases as to make its alteration or prolongation unreliable in indicating rheumatic endocarditis.

In all the cases tabulated above as cases of present or past rheumatic infection there was no question of syphilis or atheroma. I was satisfied that all were clinically true cases of rheumatic infection.

This dispensary is situated in a village, named Rattewala (Sohangarh), tehsil Muktsar, district Ferozepore. It receives patients for its 'outdoor' from the villages around, covering an area of about 48 square miles.

cases were of acute rheumatic fever and three of mitral stenosis with past history of subacute or acute articular rheumatism. Notes on these four cases are given below :—

(1) S., a Mohammedan male, 14 years of age, was admitted on 31st July, 1935, with severe pain in joints and high fever (102.1°F.). The illness started seven days ago with discomfort and slight pain in the small joints of both feet. Two days later the pain became worse and the patient was laid up with high fever. The knee, ankle, and wrist joints became involved successively. The pain was shifting in character; ankle, knee, and tarsal joints were swollen; the left knee had fluid in it. They were so painful that even the slightest movement was impossible. Pulse was regular and 112 per minute with normal tension and full volume. Apex beat was in the fifth intercostal space in the mammary line. The cardiac dullness had increased transversely. Soft systolic bruit was present in the mitral area.

He was put on sodium salicylate, gr. 20, four times a day (80 grains per diem), to which he responded wonderfully. On admission, he could not even turn over and within 24 hours he could not sit up in bed. On 6th August the dose of the salicylate was decreased to 30 grains a day, when trouble relapsed in the right ankle and readily subsided on increasing the dose to 100 grains a day.

He was discharged at the request of his father on domestic grounds with instructions to continue taking medicine. Systolic bruit was present then in the mitral area on 13th August.

On 4th November, 1935, he was again examined and found suffering from an attack of chorea. Systolic bruit in the mitral area was present.

(2) M. S., 32 years of age, carpenter by profession, was admitted on 1st May, 1935, for pain in the joints. About a month ago his illness started with acute pain.

The joints to be first involved were the shoulders and back joints. Next the fingers and elbow joints were affected. The pain was shifting in character. The joints first involved cleared up and a fresh set was next affected. In this way the patient mentioned all the joints which at one time or other got involved. On admission the knees, wrists and ankle joints were swollen and painful. The patient was confined to bed. His temperature was 99.4°F.

There was roughening of the first sound at the mitral area, otherwise heart was apparently normal.

He was put upon sodium salicylate, a drachm a day. Pains disappeared within one week and he was discharged cured on 16th May. Since July 1935, he has been working as a carpenter, engaged in building a new ward for this dispensary.

His heart was examined again on 6th November, 1935, and found normal on palpation, percussion and auscultation. The roughening of first sound, previously present, could not be detected.

(3) S., a Mohammedan male, 14 years of age, attended the outdoor department of this dispensary on 6th August, 1935, complaining of cough and breathlessness on exertion. On examining his heart, the apex beat was palpated in the fifth intercostal space in the mammary line; cardiac dullness was found increased in size transversely, and auscultation revealed a long diastolic bruit in the mitral area. The bruit terminated in the first sound; the second sound was not heard in the mitral area.

The liver was enlarged downwards; its lower edge could be felt two-finger breadths below the right costal margin.

There was no history of acute articular trouble, which might have confined him to bed, though on enquiry his father stated that pain in the legs and back had been complained of by the patient off and on for the last two years and a half.

(4) H. C., a Hindu male, 17 years of age, was admitted to this dispensary on 7th September, 1935, for swelling of the feet, legs and ascites. He gave a definite history of subacute articular pain two and a half years ago, when he got swelling and pain of the foot, knees and later other joints. Pulse count was 116 per minute, regular, volume and tension normal and equal on both sides. Cardiac dullness was increased laterally and downwards. A faint diastolic bruit was present in the mitral area; it was better heard when examined in the standing posture. He was put on tincture digitalis and intramuscular injections of salyrgan. Paracentesis abdominis had to be performed for the relief of ascites.

During the eight years of my practice in this part of the country I have treated only three cases of chorea. Two were girls, one of whom is now 11 years old. She got the attack in January 1934. Her heart was normal then. I examined her again on 3rd October, 1935, and heard a systolic murmur in the mitral area; compensation was good and the girl was healthy otherwise.

I have not come across rheumatic subcutaneous nodules so far.

I am satisfied that rheumatic fever does exist in this country area of the Punjab. McSweeney has estimated that the proportion of children showing rheumatic heart disease in Cardiff is 5.82 per 1,000 of the school population. It was found to be 7.72 per 1,000 in Bristol, as compared with 1.28 for Bath and 1.03 for Gloucestershire. It was also reported that juvenile rheumatism is a disease of towns, as opposed to country areas, and of industrial towns in particular. Perusal of the table will show that

(Continued at foot of next column)

SIGNIFICANCE OF FLORENCE TEST FOR SEMINAL STAINS*

By RAI BAHADUR K. N. BAGCHI, B.Sc., M.B., D.T.M., F.I.C.
Chemical Examiner to the Government of Bengal, Calcutta

THE choline periodide, or Florence test, for seminal stains has been proved to be of immense value in medico-legal work and adopted as a routine test in all medico-legal laboratories.

In this laboratory the seminal stains are always examined for the micro-crystals of choline periodide as well as the spermatozoa and the result is expressed in terms of spermatozoa, viz, positive or negative according as the spermatozoa are found or not found. Too much reliance is not placed on the Florence test on account of the fact that in certain cases with a negative Florence test spermatozoa have been detected. The reason for this anomalous finding is in some cases the washing of the garments and consequent dilution of the choline-containing substance of the semen, while a few spermatozoa which happened to penetrate into the

* Being a paper read (in modified form) at the medical section of the Indian Science Congress held at Hyderabad on the 2nd to 8th January, 1937.

(Continued from previous column)

it is not less common in this rural area of the Punjab than in the towns of England.

Efforts should be made to banish the idea that rheumatic fever does not exist in the Punjab. In children the onset and course of the disease may often be subacute, and thus may be frequently overlooked, if the possibility of its existence be not kept in mind. The early recognition of this destructive disease is of paramount importance in influencing its treatment. I, therefore, take this opportunity to appeal to the authorities of the Punjab Medical Department that steps be taken to circulate instructions amongst its medical officers in charge of hospitals and dispensaries to inform them of the existence of rheumatic fever in the Punjab, to put them on the alert to diagnose typical and subacute cases, and to treat them thoroughly. The replenishment of the supply of sodium salicylate should be considered as important as that of quinine or other specifics. I am sure this will result in enormous good.

Summary

A thousand outdoor cases, attending for different ailments, were examined for the existence of rheumatic endocarditis; the results are given in the table.

Four cases are reported in detail.

I am greatly indebted to Lieut.-Col. K. R. Batra for useful advice and kind permission to publish this article.

meshes of the fabric and got entangled there were not washed out. The washing in these cases is always with cold water and without any soap as is usually done by people in the countryside during their daily bath. It may also be due to some unknown chemical changes brought about by foreign matter containing all sorts of bacteria. Whatever be the reason, the fact is there and as a result of these findings a negative Florence test alone is not considered as a confirmatory test, and a spermatozoon is always searched for in all negative cases. In cases with a positive Florence test, on the other hand, the spermatozoa have in some cases not been found in spite of painstaking searches for the same and it was therefore believed that the positive Florence reaction in the particular cases had nothing to do with semen, but was probably due to the presence of blood or pus or some other choline-containing materials which are responsible for positive reaction. But in the light of the following observations it will be seen that the significance of this test has not been properly understood and there is considerable scope for modification of the interpretation of the result.

Lately, I had an occasion to examine an absolutely fresh specimen of semen of an aspermia case in which not a single spermatozoon, live or dead, could be detected, but the choline-periodide crystals developed readily and large beautiful crystals, as obtained in normal seminal fluid, were seen under the microscope. The colour, smell and consistency and also the cellular elements of the specimen were quite normal and the man was strong and otherwise healthy. It is therefore evident that the Florence test does not depend in any way on the spermatozoa but on choline of the spermatic fluid, which contains the highest amount of choline (Fletcher *et al*, 1935). The prostatic secretion obtained by carefully massaging the prostate and avoiding the seminal vesicles as far as possible also gives a slightly positive Florence test. The choline-containing substance is therefore contained in the secretion of the testes and possibly of the prostate and the production of the crystals clearly indicates the presence of the spermatic fluid quite independently of spermatozoa.

It may however be contended that choline from other sources may cause a positive reaction but the garments which are received for medico-legal examinations exclude all possibilities of presence of any choline-containing material other than semen. Blood contains a negligible amount of choline and its presence along with semen in mixed stains does not help in producing the periodide crystals, but on the other hand interferes with the reaction and the crystals do not form in the usual course. In such cases a positive reaction is obtained with difficulty after a preliminary treatment for removal of the blood proteins (Newcomb, 1932). The faecal

stains have been found to give no positive reaction. The gonorrhœal and leucorrhœal discharges resemble the seminal stains closely and are found very often in the garments. Fresh specimens of these discharges obtained from the gynæcological and venereal hospitals were examined carefully and found to give no positive Florence reaction. Neither purulent nasal discharge nor sputum, usually found in clothes, gives any positive reaction. Under these circumstances a positive reaction may be safely taken as an indication of the presence of seminal stains only.

Cases of aspermia are of course rare, but in my experience they are not so rare as it is generally believed, and these people are quite potent sexually and are likely to be involved in sexual offences. A prolonged search for spermatozoa is therefore useless in an aspermia case, and, if the presence of spermatozoa is taken as a criterion for giving opinion as to the presence of semen as it was our practice hitherto, the opinion is obviously fallacious. The formation of choline-periodide crystals, on the other hand, indicates nothing but the presence of spermatic fluid and may therefore be taken as a true index of the seminal stains. But in view of the fact that spermatozoa are sometimes found in cases with a negative Florence reaction, a careful and prolonged search for a spermatozoon is absolutely necessary before a negative opinion is given.

Greatest care should be taken in performing the test. The concentration of the aqueous extract of the stains from the garments is an important factor and it should be borne in mind that too much dilution is always to be avoided, in spite of the fact that a solution of pure choline is stated to give the micro-crystals of choline periodide in a dilution of even 1 : 50,000. The difference in the concentration of pure solutions of choline has been found to produce a pleomorphism of the periodide crystals; as, for instance, with much diluted solution 'thin black rods', instead of the usual monoclinic forms, are obtained, while with a strong solution a precipitate of blood and dark-brown globules looking like oil-globules are formed (Booth, 1935). It has also been found that the esters of choline from the tissues do not give a positive Florence reaction, but, if an ester is hydrolysed for about two minutes with a dilute alkali (1 per cent solution of NaOH) at room temperature and then acidified with dilute hydrochloric acid, the reaction is readily brought about in suitable dilution (Booth, 1935 *loc. cit.*). The presence of an alkali also retards the reaction but the difficulty is got over by acidification with dilute hydrochloric acid. The clothes which are generally received in cases of sexual offences bear the seminal stains mixed with all imaginable sorts of filthy matter, including faeces, urine, pus, blood, gum and starch (added fraudulently to produce the

characteristic stiffness), *pan* juice (containing lime and catechu), and mud; choline is likely to be chemically changed by some unknown factors present in some of the above extraneous materials and a positive reaction may not be obtained even in well-defined cases. The possibility of a chemical change of choline should therefore be thought of and the extracts of the stains from such dirty garments should, if a preliminary test becomes negative, be hydrolysed as a routine measure with a few drops of one per cent NaOH and then acidified with dilute HCl and submitted to the test once again. This procedure has proved useful in our hands.

Considering the ease and rapidity with which a stain is examined by this method, it is of immense value when a large number of articles are to be examined daily. A careful search for spermatozoa under the microscope is very trying and it takes an unusually long time to detect a spermatozoon in badly-preserved garments, specially during the wet months of the year when the stains remain moist for a considerable time; the garments are packed up without drying them properly and, as a result, bacterial decomposition sets in and the spermatozoa are disintegrated beyond recognition. Choline is left unaltered in these conditions and gives a satisfactory positive Florence reaction showing its value as a chemical method of detecting spermatic fluid. As time is an important consideration in laboratories where a large number of articles are examined the

chemical test for detection of semen is really a great help to the analyst.

In conclusion, I would like to thank Dr. S. K. Ganguli, M.B., D.T.M., for rendering valuable assistance in the course of this investigation.

Summary

Spermatic fluid always gives a positive Florence test, which does not depend upon the presence of spermatozoa, and is obtained equally well in cases of aspermia. Gonorrhœal pus of men, leucorrhœal discharge of women, nasal discharge, sputum, fæces, etc., which are likely to be found in the garments, do not give a positive reaction. Therefore, a positive Florence test is good enough for an opinion that the stains are of semen and search for spermatozoa is useless. A negative Florence test, on the other hand, does not always indicate absence of semen, and in such cases a thorough search for a spermatozoon is necessary. Hydrolysis of the watery extract of the stains with dilute alkali and subsequent acidification with hydrochloric acid helps in some cases to produce a positive reaction by liberating the free choline. Choline periodide is pleomorphic—depending upon the concentration of the extract.

A Mirror of Hospital Practice

CARCINOID TUMOUR OF THE APPENDIX

By M. M. CRUICKSHANK

LIEUTENANT-COLONEL, I.M.S.

General Hospital, Madras

THE comparative rarity of carcinoid tumours of the appendix justify the report of a case presenting certain atypical features.

A girl, aged 19 years, was admitted into the hospital on 20th March, 1936, complaining of pain of ten days' duration in the right iliac fossa. The pain had commenced in the lower abdomen, had settled in the right iliac fossa, was accompanied by a feeling of nausea, but there was no vomiting. Pulse and temperature were normal and, apart from a certain discomfort on deep palpation in the right iliac area, nothing abnormal could be made out on examination.

The patient expressed herself as perfectly well and three days later left the hospital, refusing operative treatment for what was definitely a mild attack of appendicitis.

On 14th May, 1936, she was readmitted suffering from a similar attack, which had commenced the previous day with intermittent pain in the right iliac fossa, this time accompanied with nausea and vomiting. Pulse and temperature were normal and again, apart from local tenderness on deep palpation, nothing very definite was elicited.

On 15th May appendectomy was done under general anaesthesia, through a right paramedian incision.

The appendix was retrocaecal, possessed a very limited and narrow meso-appendix, was short and thick (about 2½ to 3 inches long and ½ an inch in diameter) and firm with a uniformly smooth greyish-white surface, not unlike a small sausage stuck on to the caecal wall. The appendix was so firm right up to the caecum that the clamp had to be placed tangentially across the caecum rather than on the stump of the appendix, otherwise the appendectomy presented no unusual difficulty.

On cutting into the specimen it was noted that it felt hard, though not gritty, to the touch. The lumen was practically non-existent and signs of acute inflammation were not evident. The cut surface showed definite patches of yellowish colour. The specimen was sent to the pathologist, Dr. Vasudevan, to whom I am indebted for the following report:—

'The submucous tissue is markedly thickened and fibrosed and shows numerous newly-formed blood vessels with marked perivascular infiltration. There are also collections of plasma cells and eosinophiles. This cellular infiltration is also seen in the muscular and serous layers.

In another section, in addition to the changes described above, in the serous layer are seen collections of spheroidal cells arranged in groups, in places showing alveolar arrangement. A few of the cell groups are infiltrating the muscular layers but are absent in the submucous and mucous layers, and the appearance is not unlike that of scirrhous such as is seen in the breast.

No mitotic figures are to be seen.

A section stained by silver impregnation shows the presence of argentaffine cells.

Discussion

This specimen is peculiar in (1) that the carcinoid appearance and solid alveolar arrange-

High power.

ment of spheroidal cells are absent from the mucous and submucous layers, but present in the serous layer, and (2) that the lesion is not

Low power.

confined to part of the appendix but is distributed throughout its length.

The characteristic features of a carcinoid tumour are :—

(1) The yellowish colour of the cut surface on naked-eye examination. On cross-section a

yellow ring encircles the appendix and appears to lie in the submucous coat. The yellow colour is due to a lipoid material similar to that found in the cells of the adrenal cortex and in xanthoma cells.

(2) The microscopic picture suggestive of carcinoma, viz, spheroidal cells arranged in solid alveolar masses usually in the mucosa and submucosa, but sometimes penetrating to the muscularis and even as far as the subserosa. The cytoplasm of the cells may be granular or may be vacuolated. That these contained granules may stain intensely with silver has raised much speculation as to the histogenesis of this type of tumour, because, while demonstrating this fact, Masson has also shown that the Kulchitzky cells in the glands of Lieberkühn in the intestine stain in a similar manner. Masson's view is that the carcinoids of the appendix and intestine arise from these Kulchitzky cells, which belong to the chromaffin system, and because of their silver-reducing property are known as argentaffine cells. These cells arise from the epithelium lining the glands of Lieberkühn and migrate as a result of some stimulus, perhaps an inflammatory process, into the nerves and become argentaffine. The age incidence of carcinoid of the appendix is early, and though invariably benign in the appendix, it is probable that all carcinoids are potentially malignant.

HÆMATOKOLPOS AND HÆMATOMETRA

By R. L. SONI, M.B., B.S., F.R.H.S.

The Soni Clinic, Paungde, Burma

M. K., a Burmese girl aged 15, had some 'colicky' pains in the lower part of her abdomen towards the evening of the 3rd September, 1935, and to relieve her she was given a purgative. Next morning she purged and while straining down noticed some blood-tinged mucus coming from her rectum. The pains continued and became worse and were associated every now and then with the expression of some blood and mucus. She was given home remedies for dysentery but she made no progress and when I saw her she had suffered continuous pain for two days and three nights.

The girl was crying out with pain, sitting on the floor with her body bent forwards and her hands clenched into her abdomen. At intervals she would sit quietly for some minutes but the pain recurred. She complained of severe persistent backache, gripping pain in the abdomen and at intervals a sudden severe pain below her umbilicus and in the rectal region. She had had two somewhat similar though mild attacks, each lasting for some three days—the first two months earlier and the last three weeks ago. She had not yet commenced menstruation and there was no history of urinary retention though of late she had noticed unusual frequency.

Examination.—Nothing abnormal was detected in the abdomen except in the hypogastrium where there was a hard, rounded, somewhat tender, intra-abdominal

swelling rising from below and extending some four-finger breadths above the symphysis pubis, like an enlarged uterus. The labia minora in their lower halves were fused together to form a bulging pouch which contained foul-smelling soft matter at the top and phosphatic concretions at the bottom. The pouch was cleared of its contents, irrigated with iodine lotion and cut open in the middle line between two artery forceps. No vaginal opening was evident nor did any appreciable bulge mark its site, but the place was tense and excoriated. Rectal examination revealed congested veins and a tense, large, globular swelling which occluded it from the anterior. The finger could easily be passed behind it but anteriorly it was obstructed some two inches from the anal orifice. No waves of contraction could be elicited on recto-abdominal palpation. The finger returned stained with blood and mucus.

Operation.—After emptying the bladder and cleaning the parts with acriflavine, under local infiltration anaesthesia the site corresponding to the vaginal opening was incised and the dissection carried up in the median line. A prominent bulge made its appearance at a depth of about an inch. Under spinal anaesthesia the bulging mass was separated all round to some depth, and this dissection was considerably helped by a finger in the rectum and a catheter in the bladder. As the dissection proceeded the mass itself protruded more and more till it almost reached the skin surface. It was desired to reinforce the recto-vaginal space, which had thinned down, but this could not be done for lack of working space, which was at this stage wholly occupied by the bulging sac. The sac was loosely stitched to the sides and punctured, and tarry odourless fluid flowed out in a stream. The flow was regulated by an artery forceps in the puncture, to avoid the danger of collapse from sudden decompression. About two pints escaped in about 1½ hours when she sweated profusely, complained of giddiness and her pulse was found to be thready. Half a c.c.m. of pituitrin relieved her. The forceps were now withdrawn and the fluid allowed to ooze out unchecked.

A loose diaper was kept on and she was advised to change it frequently. Also an ergot-quinine mixture was prescribed.

Subsequent course:—

The tarry fluid continued to come out for about 20 hours and then there was a reddish flow lasting for another two days.

On the fourth day the uterus was not palpable abdominally. The vaginal wound was inflamed, the stitches had given way, and the temperature was 100°F. The lower part of the vagina was packed with gauze soaked in B. I. P. P. and the pack changed every morning for a week. Examined later the wound was found to have healed and the vagina appeared normal except for a copious white discharge. The cervix was normal and the uterus firm and in its proper place. The tubal regions were also found normal on bi-manual palpation and the bulge into the rectum was absent.

The next menses occurred after 27 days and lasted for two days. It was scanty and associated with backache. She was given freshly-prepared calcium lactate in mixture and liquor asoka and advised to take plenty of fresh vegetables, milk and fruits. The three menses that followed were somewhat irregular but for the last six periods she has been quite regular and normal.

Comment.—Cases where hæmatometra is superimposed on hæmatokolpos are comparatively rare and may be taken to be due to failure of early recognition of the condition. In this case it appears that the lower part of the Mullerian duct had failed in canalization though the remaining parts of the genital tract above it appear to have developed normally. The pouch formed by the lower parts of the labia minora is of interest, but it cannot be

definitely stated whether it was a congenital malformation or the result of an acquired adhesion, though the appearances were suggestive of the former. The phosphatic concretions were most probably derived from the ammoniacal decomposition of urine.

STONE IN THE URETHRA OF A BABY

By RAMENDRA K. BASU

Civil Assistant Surgeon, Kishanganj, District Purnea

A boy, aged ten months, was brought to me with the history that he had not passed urine for several days.

The child was in obvious distress and the bladder greatly distended and tender. The penis was erect and on palpation a hard mass could be felt near the anterior end of the urethra. Urethral obstruction was confirmed by failure to pass a fine rubber catheter further than the obstructing mass.

The child was lightly anaesthetized and the obstructing body worked forward to the meatus by external manipulation. The meatus was incised sufficiently to expose the point of the obstruction which was then removed by leverage with the single blade of a Spencer-Wells artery forceps.

The urine was drawn off with a fine rubber catheter and the meatus sutured with fine silk. The urine was turbid and was found to be heavily charged with oxalate crystals.

Next day the prepuce was very oedematous causing obstruction to the passage of urine, so the child was circumcised after which he made a complete recovery.

The foreign body proved to be a calculus the size of a black pepper, of dark brown colour, and nearly round.

I am reporting this case as it must be very rare for so young a child to develop a stone.

CALCIUM OXALATE CALCULUS IN THE URETHRA

By S. N. MITRA, I.M.F.

Medical Officer, Namdang Tea Estate Hospital, P. O. Margherita (Upper Assam)

A MALE, aged about 40 years, employed as a 'line' chowkidar, was admitted into the hospital on the 7th September, 1936, with the following symptoms:—

Frequency of micturition for one year, the quantity passed on each occasion being very small and pain and irritability of the glans penis. These symptoms had become much worse during the past four or five days. There was a slight muco-purulent discharge from the meatus and microscopical examination revealed intracellular diplococci.

A soft rubber catheter was passed and was arrested just three-quarters of an inch behind the glans penis by a hard mass which could be felt on external palpation. It was extracted by artery forceps after breaking it into four pieces and it was identified as a calcium oxalate calculus. The total size of the stone was three-quarters by half an inch, irregular, very hard, and dark brown in colour. The patient was relieved of his symptoms and no further stone could be detected either in the bladder or in the urethra.

The man has lived in the garden for over 20 years. There is no previous history of any continuous fever nor any family history of calculus. He is much addicted to drinking country liquor and chews a great deal of betelnut.

Indian Medical Gazette

FEBRUARY

COD-LIVER OIL IN SURGERY

ABOUT three years ago Professor W. Löhr reported, at a Medical Congress at Magdeburgh, the remarkable results he had achieved during the previous two or three years by the use of cod-liver oil in the treatment of septic lacerated wounds, compound fractures, acute osteomyelitis and burns; in short in any conditions where pyogenic infection plays an important part. He first tried cod-liver oil dressings because he had formed the impression that wounds healed better in children who were taking cod-liver oil internally than in those who were not having it, and his results were so promising that he soon adopted this method of dressing as a routine treatment for practically all septic conditions. In addition to oil dressings he employed the usual surgical procedures, such as free evacuation of pus and excision of dirty wounds, before filling the cavity with cod-liver oil and covered the area by a plaster splint to ensure immobilization of the part if such were necessary. Unless there were indications for its removal, this dressing was left in place for about a fortnight without renewal.

This work of Löhr's was altogether empirical and all the explanation offered for the good effect of cod-liver oil as opposed to other oils was that it contained an unspecified 'something' which other oils lacked. Such remarkable results naturally attracted a good deal of attention and it was not long before other reports began to appear confirming Löhr's claims, and in England Steel of Liverpool gave an account of his experience in the use of this oil in treating burns and showed that the healing under dressings of cod-liver oil was much better than under tannic or picric acids, the remedies that have been considered the best for several years in the relief of these painful injuries.

So far no attempt had been made to identify specifically the active principle responsible for the healing powers of cod-liver oil, but it was a foregone conclusion that this form of treatment would not be allowed long to remain on this rule of thumb basis and that research workers would soon attempt to solve this problem, and so provide a sound scientific explanation for the facts which had been amply established by clinical observation.

Papers on this aspect of the subject have now begun to appear and among them are two in the *Lancet* of September last year. It is natural in times, such as the present, when vitamins loom so large before us that the well-known high vitamin-A content of cod-liver oil should

be considered as the first possibility to be investigated. The first of the papers quoted above is by Davson at Manchester University, and as a preliminary he performed experiments to show that cod-liver oil was definitely a more active stimulant to tissue response than other oils. He injected into rabbits' ears cod-liver oil, olive oil and paraffin and it was clearly demonstrated that the tissue reaction surrounding the cod-liver oil globules was much more active and led to the production of more completely organized new tissue than in either of the controls. With the idea of finding out whether vitamin A was the responsible agent, a second series of experiments was performed using cod-liver oil and halibut-liver oil, because the latter has a much greater vitamin-A content than the former. Both these oils were used undiluted and diluted 1 in 20 in olive oil, and pure olive oil was used as a control. It was found that halibut-liver oil, with approximately one hundred times as great a vitamin-A content as cod-liver oil, was no more active than the latter either in the pure or in the diluted state. It is concluded by this worker that vitamin A is not the important factor and two other possibilities are suggested. One is that animal oils are more rapidly and completely hydrolized in animal tissues than are vegetable or mineral oils, and the other is that vitamin D, which is present in approximately equal proportions in cod-liver and halibut-liver oils, may be the active principle.

The second paper to which we have referred is by Sandor in Hungary and altogether disagrees with the above conclusions, for it is claimed that pure vitamin A without any vitamin D, and mixed in an inert base such as paraffin in the form of an ointment, is just as effective as cod-liver oil, so that Sandor and the group of workers associated with him ascribe the therapeutic value of cod-liver oil to vitamin A alone.

As is to be expected cod-liver oil or its manufactured substitute, known as vulnovitan, is being tried on all kinds of conditions. There are several reports of its value in clearing up eye infections of many kinds and in promoting the healing of indolent corneal ulcers. It is claimed that cutaneous ulcers with large granulating surfaces and no tendency to heal, under cod-liver oil after an intense cellular reaction lose these granulations and are replaced by healthy healing tissue.

The group of workers associated with Sandor report on the successful treatment of cases of surgical tuberculosis and even of gastric and duodenal ulcer. These numerous uses of cod-liver oil indicate that as a new and apparently valuable remedy for external application it most probably will be tried and possibly claimed as a cure for all the ills to which flesh is heir. We have had some small experience of this form of treatment, both in pyogenic skin diseases and

anal fissure, and have been favourably impressed with it.

It will of course not fulfil all the expectations of the uncritical enthusiast, but there is little doubt that when its powers have been properly

assessed it will be found a valuable substitute for more irritating antiseptics and will prove an important addition to our collection of external medicaments for a certain number of diseases.

Special Article

FAIRS AND FESTIVALS IN INDIA*

By R. B. LAL, M.B., B.S., D.P.H., D.T.M. & H., D.B.

Officiating Director, All-India Institute of Hygiene and Public Health, Calcutta

MAN, says Aristotle, is a social animal. We gather together for purposes of social intercourse, for celebrating fairs and festivals, for transacting business, and unfortunately also for waging wars. In doing so not only do we exchange our sentiments and feelings, our wares and our bullets, but also, unless we are particularly careful, we unwittingly exchange our respiratory and intestinal flora, and ectoparasites. Exposure to infection in this manner starts early in life, but as we grow older our contacts in the daily round increase and the spheres of the sources of infection enlarge and we contract many a common malady. The common cold is an example. However, under settled conditions of life, partly on account of natural adjustment of the herd resistance and partly to conscious communal efforts, the evil effects of this exchange of flora are, in a civilized community, very much minimized. In large gatherings, on the other hand, all safety measures are liable to break down with dire consequences. It is under these circumstances that the technical knowledge, the administrative capacity and the resourcefulness of the public health official are taxed to their fullest extent. To escape from disastrous epidemics, therefore, we must look up to the health administrator for his thorough understanding of the problem, foresight, attention to minutest details, qualities of leadership and physical capacity on the one hand, and on the other to the confidence reposed in him by the community in the form of co-operation, investment of legal powers and provision of material resources.

The slow but steady development of international rules of health and the administrative machinery set up to enforce them have, to a great extent, banished the dangers arising out of the communicable diseases in relation to trade and travel though the increasing speed of modern transport is every day creating new

problems. Again, the recent advance in military hygiene has removed the horrors of war so far as the epidemic diseases are concerned.

The problem of the management of the fairs is much more difficult to solve. The public health official possesses neither the dictatorial powers of the military hygienist, nor the material resources of the Port Health Officer. The pilgrim centres in this country draw their religious devotees in millions from all parts of the country; each individual contributes his own quota of infection peculiar to himself. His religious fervour is great, but his material resources are scanty. He is half starved and possesses but little means of protection against the inclemency of the weather. His ignorance on the one hand and the avarice of the priests and other opportunists on the other conspire to dispose of what little he does possess. He is not used to any discipline and is in no mood to co-operate with the authorities. Besides, he finds himself in strange circumstances where he is unable and unwilling to abide by the few rules of health which he was in the habit of performing. Thus in a fair we have congregations of an undisciplined mass of humanity capable of generating a large quantum of various kinds of infection. They possess little or no resistance due to lack of previous experience of the infection or due to malnutrition, nervousness and hardship. They are huddled together under ideal conditions for the spread of the infection. It is little wonder, therefore, that fairs and pilgrim centres have acquired a notoriety in the history of epidemic diseases in this country and are justly dreaded by health authorities as starting points of widespread epidemics. Not only is the place of congregation the danger spot, but the nodal points along the pilgrim routes are sources of equal anxiety to the health administrators. These camping grounds or temporary abodes, where confluence of the stream of pilgrims arriving from different routes takes place, are also hot-beds of epidemic diseases. They are much more difficult to manage than the fair grounds themselves.

Epidemics of cholera have time and again been traced from the pilgrim centres, such as Hardwar, Allahabad and Puri, but many other epidemic diseases, less dramatic in their manifestations and more difficult to trace, must also arise in connection with the fairs. Records are

*Being a lecture delivered at the Public Health Society, Calcutta, on the 18th December, 1936.

We hope to publish a similar lecture on some public health subject each month during the year.—EDITOR, I. M. G.

full of such happenings. It is, however, not my intention to dilate on this point, but the history of cholera in the Punjab in relation to the Kumbh and the Adha-Kumbh fairs at Hardwar is a clear demonstration of the rôle of the festivals in the causation of this epidemic disease. Similarly, at Allahabad, each and every gathering at the time of the Kumbh and Adha-Kumbh from 1882 to 1918 was accompanied by a great rise of cholera incidence in the eastern districts of the United Provinces, Bihar and Orissa, and the Central Provinces. The Ratha Jatra fair at Puri, Sinhasht fair at Nasik and Godavari, Puskaram fair at Rajamundry, Krishna Puskaram at Bezwada, Mahamakshan fair at Kumbhakonam and Sagor Mela in the Sundarbans occupy no less enviable position in relation to cholera epidemics. Some of the epidemics in connection with these fairs have led to world-wide epidemics. It must, however, be remembered that it is not only these mammoth gatherings which are sources of danger, but, as the pilgrim committee of Madras have rightly pointed out, the smaller festival centres in out of the way places are of no less importance.

The festival centres may conveniently be divided into :—

- (a) the places of perennial pilgrimage, and
- (b) temporary camps specially erected for periodical fairs and festivals.

The former possess some special religious sanctity apart from the occurrence of holy days. They continually attract pious people from different places. Kalighat, Benares, Puri, Rameswaram and many others may be cited as examples of such centres. The latter type of centre comes into prominence only on certain days in the year and, more particularly, periodically after a number of years. The attractions to these places are as much secular as religious. Kumbhs and Adha-Kumbhs at Hardwar and Allahabad are the best examples. Ardhodaya Joga festival on the Ganges and the Sagor Mela, the Puskaram fairs along the bank of the Godavari and Krishna are also similar in nature. Names of some of the important fairs held in different provinces along with average number of persons attending them, the time of the year when they are held, and the duration of the festivals are shown in the annexed table which may be of interest.

Control measures

Although the importance of the fairs in the spread of infection, particularly of cholera, was recognized long ago, it was only in recent years that earnest attempts were made to control them. People were used to looking upon these happenings as inevitable and the magnitude of the problem used to scare away the not-over-enthusiastic health officials. Even such a forceful personality as Sir Leonard Rogers once considered the sanitary control of fairs too

stupendous a task to be attempted with any chances of success. Thus, for a long time the custodians of the health of the people totally ignored the occurrences of the fairs. Dr. C. Plank, then Sanitary Commissioner of the United Provinces, for example, was unaware of the occurrence of the Kumbh fair, held at Allahabad in 1882, until he noticed a large number of people travelling by road to the fair grounds on the south-west of the city. The first determined attempt to move in the matter may be seen in the Puri Lodging House Act of 1871 which is in fact the precursor of the Bengal Municipal Act of the present day. Earlier attempts were mainly in the nature of medical treatment of minor ailments amongst the pilgrims. The medical subordinates who were deputed to these duties were neither capable nor properly equipped to cope with any serious outbreak of infectious disease. Up to the beginning of the present century the state responsibility in the control of the infectious diseases at the pilgrim centres was only partially recognized and it was left mainly to the local authorities to do what they could in the way of sanitary control of fairs. Sanitary inspectors were put in charge of public health organizations at the fair grounds and their efforts usually ended in complete failure. Apart from the insufficiency of funds and the lack of expert direction, the main reason for these failures was that no attempt was made to control the nodal points. Meanwhile the epidemic diseases continued to play havoc with the pilgrims. Pilgrim committees were then appointed in Madras, Bihar and Orissa, Bombay, United Provinces, etc., and their reports were forwarded to the Government of India in 1916 by the Sanitary Commissioner with the following remarks :—

Medical arrangements on railways :—

Along all the main lines there should be properly appointed stations where patients must be removed if suffering from any infectious disease. They should not be removed at places where no facilities for treatment exist. On the whole, all the pilgrim committees consider that the railway should be responsible for removing the patients and sending them to the hospital, but it is advisable to have the hospitals under the local civil authorities.'

This was the beginning of the suggestion of the much-needed joint action by the various public health authorities. The decentralization of sanitary services effected by the Reforms Act of 1919 threatened to kill this germ of joint and organized action by different provinces and other bodies responsible for the health of the people. Luckily, however, the provincial public health departments recognized the importance of joint action and successfully extended this principle to certain fairs of all-India importance. How successful such a policy has proved to be is best illustrated by the brilliant achievements

at the Kumbh and Adha-Kumbh fairs held at Allahabad in 1930 and 1936 respectively. I attended the Adha-Kumbh fair held early this year at Allahabad, and a short account of this fair will, I think, be of interest.

A fair is held annually at the confluence of the Jumna and the Ganges south of Allahabad, during the months of January and February. It assumes special importance every 12 years when it is known as the Kumbh fair. In between two Kumbhs, Adha-Kumbh fairs are held which are somewhat less important than the former and usually attract a smaller number of people. Thus the Kumbh and the Adha-Kumbh alternate at an interval of six years. The 1936 Adha-Kumbh began on Puranmashi day on the 8th January and lasted for one full month up to the next Puranmashi, *Makar Shankrant* on the 14th January, *Amawasya* on the 24th January and *Basant Panchami* on the 28th January were the chief bathing days on which the expected number of bathers were estimated as 200,000, 1,500,000 and 500,000 respectively. Actually, however, a much larger number visited the fair. The resident population in the *mela* area was expected to be in the neighbourhood of 30,000 on *Makar Shankrant* and 50,000 on the *Amawasya*.

For the sake of convenience the public health arrangements may be divided into three parts :—

(1) Prevention of importation of infection into the *mela* area and the control of nodal points in connection with the incoming pilgrims.

(2) Sanitary control at the fair grounds.

(3) Prevention of the spread of infection through the returning pilgrims.

To ensure the co-operation and joint action by the public health services of the adjoining provinces and of the railway authorities a joint meeting of the Directors of Public Health of the Punjab, United Provinces, Bombay, Central Provinces, Bihar and Orissa, and Bengal and of the Chief Medical Officers of the E. I. Railway, B. & N. W. Railway, and G. I. P. Railway is held a few months before the fair. Arrangements are made to draw the attention of the intending pilgrims to the dangers involved in proceeding to the fair. They are induced to get themselves inoculated against cholera before leaving their homes. Arrangements are made at important railway stations in their own provinces for medical inspection before the pilgrims entrain for Allahabad. Similar arrangements are also made for medical inspection at boundary stations and at stations *en route*, viz, Moghalsarai, Kashi, Benares, Benares Cantonment, and Ajodhya, and also at stations in Allahabad, viz, Allahabad Junction, Allahabad Sangam, Prayag, Prayag Ghat, Phaphamu, Allahabad City, Izat Bridge and Jhusi.

At Moghalsarai, Jhusi, and Phaphamu eight, four, and one cholera beds, respectively, are provided in huts specially erected for the purpose

with the object of segregating the pilgrims found to be suffering from cholera. Four additional smallpox beds are provided at Moghalsarai. The patients detained at other railway stations are removed to the nearest municipal infectious diseases hospital, the railway infectious diseases hospital at Naini or the special infectious diseases *mela* hospital, as the case may be. For pilgrims travelling by road arrangements for the detection of cholera and smallpox cases and their detention in suitable hospitals are made at Jhusi on the Grand Trunk Road, at the junction of Grand Trunk Road and Fort Road, at the bund near the Mori-Daraganj and at the junction of the Bund and the Tribeni roads near the carriage stand. A party consisting of a medical officer, a peon, two vaccinators and one sweeper is posted at each of these places. A supervising medical officer is also appointed to maintain these services efficiently.

The district boards of Allahabad, Fatehpur, Jaunpur, Pertabgarh, Mirzapur, Benares and Faizpur are made responsible for the repairs of roads, camping grounds, wells and tanks situated within their jurisdiction. The wells are disinfected before the commencement of the *mela* and this service is repeated as often as necessary. At the recommendation of the Director of Public Health grants-in-aid are given by the Government to these boards for the improvement of the wells. The municipal boards of Allahabad, Benares, and Faizabad are asked to augment their medical and sanitary staff and enforce sanitary measures in connection with the temporary camping grounds for pilgrims within their limits. Special attention is paid to the prevention of over-crowding and to the provision of proper sanitary arrangements in the *sarais* and other lodging houses. A watch is kept for the detection of cases of infectious diseases.

The *mela* area consists of the beds of the two rivers. It is a triangular piece of land, the base of which is formed by the Fort Road, and the two sides by the Jumna and the Ganges. The Izat Bridge on the Ganges and the Jumna Bridge form the upper limits and a point half a mile below the confluence of the rivers the lower limit within which they are under sanitary control. Jhusi village across the Ganges and Arail on the other side of the River Jumna are also included in the *mela* area. Soon after the rains this area is cleared and laid out for the *mela*. It is divided into five sanitary circles :—

Circle I the area above the bund.

„ II Ganga Patti.

„ III Jumna Patti.

„ IV Jhusi.

„ V Arail.

The central road, which is the continuation of the Tribeni Road, separates the Ganga Patti from the Jumna Patti. Each circle is laid out into small square or oblong plots surrounded by cross roads. In circle I, general offices,

exhibitions, *sabha pandals* and parking grounds are located while in the other circles plots are allotted to different parties of pilgrims, the requirements of the bigger parties and *akharas* having been ascertained beforehand.

Conservancy.—Public latrines are provided in the form of trench latrines which after use are filled in with mud and a layer of lime over which is placed a covering of gunny bag soaked in tar. Additional clay is heaped up and painted white to prevent persons from trampling over them. Each trench is 72 feet long, 1 foot wide, and 4 feet deep and accommodates 24 seats. Two hundred trench latrines in 40 sets of 5 each are provided yielding a total of 4,800 seats. To prevent caving in of the walls planks of wood are laid on either side of the trench. They also act as foot-rests. Private latrines of similar type are permitted in special cases. A hydrant is fixed near each trench. Sweepers are in attendance at all latrines to keep them clean, to fill up the used ones, and to dig new trenches. The trench latrines answer the purpose very well and are quite popular except with a certain sect of *sadhus* who refuse to use them. For this group enclosures known as 'flagged areas' are provided from where excreta are collected by sweepers and removed to the nearest trenches. No promiscuous defiling of the grounds is permitted. This is accomplished with the help of sanitary police.

Four hundred urinals are provided in suitable places. They consist of small enclosures in which an oblique funnel-shaped tube is buried in the ground, the lower end of which opens in a soakage pit.

Rubbish and garbage are collected by the conservancy staff and deposited in dust-bins placed at suitable locations. The contents are removed to rubbish pits, 60 of which had been provided. The final disposal is effected by burning on the spot. A quicker disposal of rubbish could probably be accomplished by providing tubular openings at the bottom to act as under-drafts.

With the sacred bathing, the ceremony of shaving the head is linked up. This operation is permitted only in a special enclosure, known as *Naibara*, where sweepers are detailed for collecting the hair in gunny bags and removing it to boats for dumping in the river at some distance down the confluence. Special *domes* are engaged to remove the animal corpses and unclaimed dead bodies for disposal. The cremation is performed at the *ghats* on the bank of the Ganges.

Water supply

Water is derived from two deep tube-wells which are permanent constructions above the *bund*: each yields 2,500 gallons per hour. The water is stored in an overhead reservoir from which it is distributed throughout the area, particularly along the banks of the river.

Medical relief

A large area on the Jumna Patti is enclosed to house the main hospital for general diseases. The outdoor department is situated on the main road. Altogether 90 beds are provided, 20 of which are reserved for women and 10 for the police force. The indoor accommodation takes the form of small isolated huts accommodating four beds each. This arrangement is cumbersome from the administrative point of view, but it has been adopted as a precautionary measure against an outbreak of fire—the huts being made of dry hay stalks and bamboos.

An outdoor dispensary is also provided for the use of the police force in circle I.

A similar 90-bed hospital is located in the Ganga Patti. This serves as the infectious diseases hospital. A Servian-barrel disinfecter has been set up in the compound. Exposure to cold winds is, however, likely to reduce its efficiency. Only three cholera cases were admitted into this hospital during the fair. A camp laboratory is attached to this hospital.

Besides the two main hospitals there are two branch hospitals at Jhusi and Arail. The former consists of four beds for infectious diseases and four for general diseases. At Arail there are only six beds, two being reserved for infectious diseases.

Ambulance services have been provided.

Voluntary aid.—*Sewa Samity* provides first aid and arranges to remove the patients to the hospital. Three dispensaries have been opened by voluntary agencies where free treatment is given.

Light.—Electric light has been supplied throughout the *mela* area. This is a great improvement on previous *melas* inasmuch as it reduces the chances of fires and greatly increases the efficiency of the conservancy staff and the sanitary police.

Dust nuisance.—Adequate arrangements have been made for watering the roads and there is no dust nuisance.

Public health propaganda.—Advantage has been taken of this gathering for purposes of public health education. An extensive and attractive exhibition has been organized by the Assistant Director of Public Health Propaganda. The model demonstrating the efficiency of quinine in malaria is particularly impressive. Many lectures on public health topics are broadcasted by the aid of a megaphone. Cinema films are shown at night. A film describing the *Pertabgarh Health Centre* is particularly interesting. These films attract large crowds who have to sit there for hours. There is a possible danger of exposure to cold in the open *maidan* where these demonstrations are held.

General administration

An Assistant Director of Public Health is in general charge of the sanitary and medical arrangements. He possesses extensive powers

List of important fairs and festivals in India (by provinces)

Serial number	Province.	Name of the fair	Locality	Permanent or temporary	Number of persons attending	Interval at which held	Duration	REMARKS

under the Indian Epidemic Diseases Act, 1897. He is assisted by a deputy and by medical officers in charge of circles. Special medical

officers have been detailed for hospitals, field laboratory and supervision of arrangements at the railway stations in Allahabad. The medical

officers in charge of the circles are assisted by vaccinators, jamadars, beldars, mates, and menials in the discharge of their duties. Besides proper maintenance of the sanitary condition of their areas, these officers are responsible for the detection of cases of infectious diseases and their removal to the hospitals.

I have tried to give you a brief sketch of the medical and sanitary arrangements made at the Adha-Kumbh mela held in January and February 1936, but an adequate idea of the success of these measures can only be obtained by a personal visit. The standard of general cleanliness is very much higher than in an average Indian town. Flies are conspicuous by their absence. The danger of extension of an epidemic is reduced to a minimum. The pilgrims feel safe and comfortable. These fairs may, in fact, be looked forward to an occasion

for physical and mental rest as much as a source of spiritual gain. This is no mean achievement. Rai Bahadur Dr. K. P. Mathur, the present Director of Public Health, United Provinces, who as Assistant Director was in charge of the sanitary and medical arrangements of the fair, is to be congratulated on his successful administration and also his staff.

Time does not permit me to dwell on the sanitary arrangements at a centre of perennial pilgrimage but what I have said is enough to show how much can be accomplished in the way of saving human life and enhancing the happiness of the masses under most difficult circumstances, if only an earnest attempt is made under suitable direction, and the community places sufficient funds of goodwill and material resources at the disposal of public health authorities.

Medical News

THE SOCIETY FOR THE STUDY AND PROMOTION OF FAMILY HYGIENE INCLUDING SEX HYGIENE

THE Society for the Study and Promotion of Family Hygiene gives training in practical contraception to doctors and nurses who are members of the society. The fees are Rs. 25 for doctors and Rs. 15 for nurses in addition to the membership fee of Rs. 12 a year.

The society has also for hire to medical groups three cinema films on the technique of birth control including demonstrations on a living subject, the hire charges being Rs. 50 only.

For particulars apply to the General Secretary, Kodak House, Bombay 1.

PRESIDENTIAL ADDRESS TO THE BENGAL PHARMACEUTICAL ASSOCIATION

GENTLEMEN,

It is my duty in the first instance to express my appreciation for the honour you have done me by asking me to be your president for the second time during these few years. My duties at the School of Tropical Medicine make such a heavy demand on my time that I felt considerable hesitation in accepting it. My interest in the question of organization of the profession of pharmacy in India has, however, prevailed upon me once more to accept your offer. At the same time I cannot help feeling that perhaps someone with more leisure could have been found who would have done justice to the duties and responsibilities connected with this office at a time when important changes are taking place in order to lay the foundation for a profession of pharmacy in India. For my part, I can assure you that so far as it lies in my power, I will, with your co-operation and help, do my best to further the interests of the association.

It is with a sense of deep sorrow that I refer to the untimely death of Mr. H. Cooper. A member of the Pharmaceutical Society of Great Britain, engaged in manufacturing pharmacy in India for well over a decade, Mr. Cooper was genuinely interested in the uplift of the pharmaceutical trade, profession and industry in this country. At my request he undertook the onerous duties of guiding the destinies of the Bengal Pharmaceutical Association during the first year of its existence. At this formative stage when the Association needs

guidance from a pharmacist of mature experience and ripe judgment, such as Mr. Cooper could give, his death is most unfortunate and regrettable. I feel it as a personal loss, as he was not only a friend but a member of the Drugs Enquiry Committee over which I had the honour to preside a few years ago. Before that he was also associated in the work the School was doing in connection with the important problem of investigation into the drug resources of India. We deeply regret his loss and offer our sincere and respectful condolences and sympathies to Mrs. Cooper in her bereavement.

The root of the evil

In 1934, when I was elected your president, I had the honour of presiding at your annual meeting in this very hall. Your association was called the 'All Bengal Compounding Association'. You decided at that time to change the name to 'Bengal Pharmaceutical Association' and this change of name brought with it a significant change in the activities of the association, that was undoubtedly a move in the right direction. Though at the present time no organized and self-contained profession of pharmacy is in existence in India as in other civilized countries, during the last two years there has been unmistakable evidence of an urge on the part of the association to improve the existing conditions. The evidence produced before the Drugs Enquiry Committee regarding the character and quality of the work turned out by the profession as a whole in this country was far from being complementary, as you are all well aware. The committee, after careful consideration, came to the conclusion that two things accounted for the regrettable state of affairs which existed—firstly, the lack of educational qualification of those who took up the profession and, secondly, the absence of restrictive laws preventing the practice of the profession by unqualified persons. These were the root of the evil. The committee considered that if something could be done to effect improvement in these two directions, pharmacy as a profession would be lifted from the deplorable condition in which it found itself and would be able to take its proper place by the side of the honourable and dignified profession of medicine in this country.

Training of the pharmacists

During the last few decades considerable changes have taken place in the practice of the profession of

medicine. Knowledge of medicine has made enormous and rapid strides and this is reflected in the medical curriculum of the present day. The medical profession in India has tried to move with the times and has embodied and incorporated much that is necessary to build up a generation of professional men equipped to carry on the modern teaching and practice in its various branches. That is the reason why the medical profession in this country has held its place. Unfortunately the same cannot be said about the profession of pharmacy. In order to build up a profession in the true sense of the word, the first and perhaps the most essential prerequisite is training of its members. Both 'medicine' and 'pharmacy' are professions which aim to serve the public and 'to serve well' should be the keynote of both. The profession of medicine has attempted to move, as far as possible, with the changing conditions. The profession of pharmacy has lagged behind, through no fault of its own perhaps. That is the reason why it is in such a deplorable condition in India to-day. Pharmacy is intimately related to medicine and it may be said without contradiction that the practice of pharmacy is an integral part of the practice of medicine. One cannot make much headway without the other going ahead also. The present position is therefore untenable.

It is essential, therefore, that the training of the pharmacist should be improved to enable him to discharge in a full measure the responsibilities attached to his profession. He should equip himself to take his place side by side with the members of the allied profession. In Great Britain, United States of America and in many countries on the Continent of Europe, an elaborate and efficient training is enjoined before anybody is allowed to practice the profession of pharmacy. Such an elaborate system would be ideal if it could be transplanted here *in toto*. But like all ideals, it should be approached with caution. The conditions in India are vastly different and modified methods are needed to cope with the situation as it exists in this country. With full realization of all these difficulties, the Drugs Enquiry Committee worked out a suitable curriculum for adoption in India and I am glad that this association has fully supported it and has made admirable attempts to see that these suggestions are given effect to at the earliest opportunity. Your representations have borne fruit and in Bengal, at any rate, the Governing Body of the State Medical Faculty have accepted the improved curriculum and it is now before the Government of Bengal for approval. I have every hope that this curriculum, which involves a training for two years, would be found suitable and will be put into practice in the near future. As time goes on and more specific demands arise, the provisions are elastic enough to incorporate other important and significant alterations and additions.

The basic qualification and curriculum

You will all agree that a preliminary basic qualification is necessary in order to provide a basis for scientific studies. It is essential therefore that an intending pharmacist should have this basic knowledge and to enable him to do this he should possess a matriculation certificate or an equivalent qualification before beginning his professional studies. The first year should be spent in the study of elementary botany, physics, chemistry both inorganic and organic and pharmaceutical arithmetic. There is always the danger of teaching too much or too little and it is difficult to set up the exact standard. To avoid these difficulties, definite courses have been presented which will avoid confusion and meet with the requirements. In the second year's course, along with other important subjects, a course in elementary pharmacology is included. So long as it was thought dangerous to teach the pharmacist anything of the sciences on which medicine is based, so long was the pharmacist placed in a ridiculous position. It is impossible for any man to carry on his work intelligently unless he knows its purpose. It is therefore impossible for the pharmacist to prepare

and dispense medicaments intelligently unless he knows something of their nature, action and use. Recent advances in materia medica have made the truth of this statement indisputable. If the pharmacists are to discharge their duties properly they must have the knowledge to understand the principles underlying the manufacture of medicaments used in modern medicine. The days of compounding simple mixtures and of making elegant preparations by addition of flavouring agents are gone and, if pharmacists wish to keep abreast of the times, they must keep in touch with the rapid advances in medicine and pharmacology. Pharmacy should supply the knowledge concerning drugs and preparations required in medical and veterinary practice and it should move on with the new orientation of therapeutics.

Legislation—'Pharmacy and Drugs Law'

So much for the curriculum and training. But improvement in the standard of training and qualification will not be effective in the absence of restrictive laws controlling the exercise of the profession. If the properly qualified pharmacist is not protected from charlatans, it is feared none will care to enter the profession seriously and face the unfair competition. What is the present position with regard to this? Those of you who were present at the annual meeting two years ago will remember that I laid great stress on the fact that the legislature in this country has not passed any act dealing with pharmacy. The Indian Poisons Act, the Opium Act, and the Dangerous Drugs Act only partially control the manufacture, sale, possession and import of certain drugs, but have no relation to the practice of pharmacy. They do not ensure that persons selling or keeping open shops for retailing, dispensing or compounding of poisons and narcotics should possess a competent knowledge of their business. In a few provinces chemists' shops are obliged to employ qualified compounders for compounding, dispensing and selling drugs under provisions of the Municipal Acts, but in most of the provinces there are no regulations whatever. In those provinces where Municipal Acts are in existence provisions requiring the registration of shops for sale of drugs and prohibiting the practice of the profession by unqualified persons are included. In actual practice, however, the machinery to see that the provisions of these acts are enforced is very inadequate and the actual state of affairs is not much better than the provinces where there is no enactment.

Quality of drugs in the Indian market, and drug industry

There is also no legislation to control the quality of drugs; the result is that the market in India is flooded with drugs and chemicals of defective strength and impure quality by unscrupulous traders and that potent remedies such as organo-metallic compounds, sera and vaccines are being freely sold without their quality having ever been tested. It is well known that certain firms abroad manufacture cheap and inferior quality drugs specially for the Indian market and are able to undersell the local manufacturers of drugs in this country. This dumping of drugs of inferior quality has its repercussion on the quality of drugs manufactured in India in that the quality is deteriorated to keep pace with the competitive rates of dumped goods. A class of manufacturers has arisen who make and sell inferior and sometimes absolutely inactive products. This substitution of genuine medicinal products by rubbish has now reached a very serious stage and is a source of grave danger to the country.

I consider that it is the duty of an association like this to press for the necessary legislation as this question is intimately connected with the question of the organization of the profession of pharmacy in India.

Need for co-operation and self-help

Legislation is necessary but is not the only essential factor. A proper understanding and due regard for

the rights of everybody concerned are quite as important; these will act as stimuli and as correctives and will promote friendship and better service. Laws should be the expressed demands of the people as a result of interest and study of existing general good. If confidence, co-ordination and co-operation are ensured among the members of the profession the rest will follow. By improving your training, you will be able to bring better understanding amongst yourselves, and protective legislation is bound to follow in due course.

It has often been said that unless there are legal restrictions to protect the qualified pharmacist from being subjected to the unfair competition by unqualified persons, few people will care to enter the profession. A distinctive training would naturally require a distinctive treatment and, if such treatment is not forthcoming, disappointment will be the inevitable result, leading perhaps to a breakdown of the ethical standards by which alone the profession should be guided. While I fully realize the difficulties, I am one of those who believe that qualified pharmacists will be able to hold their own even without any protective legislation. As I have outlined in the Report of the Drugs Enquiry Committee legislation should have an all-India scope and should apply uniformly to all the provinces in India. Such an extensive legislation may take time. The only way to hasten the issue is to make the legislators and the public opinion in the country feel the sphere of usefulness of the profession of pharmacy. This can only be achieved by radically reorganizing the profession by improving the training of the pharmacist and fostering a spirit of service to humanity.

Drugs Control Laboratory

You are no doubt aware that the Government of India in consultation with the provincial governments have recently decided to open a Drug Control Laboratory at the All-India Institute of Hygiene and Public Health for the control of spurious drug traffic. This is the direct result of the recommendations set forth in the report of the Drugs Enquiry Committee. The establishment of this laboratory is bound to have a far-reaching effect on the profession of pharmacy in general and the drug trade in particular. By creating an effective check on the spurious drug traffic which is glutting India at present, it will exert a wholesome effect on the profession. May I venture to suggest that the present time is the most opportune for putting your house in order and for coming forward with all the help that the resources of your association can command to make the working of this unit a success. With machinery for drug control in working order, one may confidently hope that the medical profession and the public will derive immense benefit. The pharmaceutical profession, trade and drug industry will be gainers to a very considerable extent.

The future

I will not take much more of your time by going into details of many of the minor aspects of the profession of pharmacy. I have tried, in the short time at my disposal, to bring to your notice the most crying needs of the profession as it stands to-day and the means by which improvement can be effected. I have laid stress on the question of improving your training. There are some who will ask whether an improvement in training will add to a pharmacist's earnings. Will a more extended and more expensive training covering a period of two years give the pharmacist a professional income commensurate with the time and money spent on it? It may be argued by some that, after all, a pharmacist's function is to compound and not prescribe; why then should he bother about a more comprehensive training? My answer to that is that improved training will certainly bring about improvement in the avenues open for employment and will result in increase in wages. You have only to follow the progress made by the profession of pharmacy in the Western countries to see the truth of my assertion. If one pays a visit to the centres of drug manufacture

in Great Britain, Continental countries and the United States of America, one at once realizes what large openings there are for the pharmacists. The pharmaceutical industry is now making headway in India and there are bound to be openings, which will go to the pharmacists if properly trained and qualified persons are available. There will be demand for the service of trained pharmacists in hospitals, dispensaries and other public institutions all over the country. Pharmacists are being recruited in increasing numbers in the army and navy and efforts to increase their representation in the various government services are meeting with encouragement both in the United States and in Great Britain. That is bound to come in this country in the near future. The future of pharmacy in India, therefore, if it can be lifted from its deplorable position, is bright and there is no reason for a pessimistic outlook. The existing problems may be serious but are not of a nature which cannot be remedied by intelligent co-operation and self-help and genuine desire for the improvement of the status of the profession. The pharmacists should bear in mind that efficient service to the public should be their prime consideration and motto. It is reassuring to see that there is already evidence of greater interest and I believe that within the ranks of this association there are men with ability, courage, foresight and breadth of vision, who will help to solve the existing problems leading to the uplift of the profession and will cope with any which may arise in future.

R. N. CHOPRA, C.I.E., M.D., M.R.C.P.,
BREVET-COLONEL, I.M.S.,

Honorary Physician to H. M. the King.

THE TINNEVELLY DISTRICT MEDICAL ASSOCIATION, PALAMCOTTAH (AFFILIATED TO THE INDIAN MEDICAL ASSOCIATION)

Health exhibition

UNDER the auspices of the Tinnevely District Medical Association in connection with its monthly meeting at Koilpatti, on Sunday, 20th December, 1936, a health exhibition was arranged at the Loyal Mills, Koilpatti, for the benefit of the labourers and staff and their families. This was the first time a health exhibition had been held at these mills.

Lieutenant-Colonel T. S. Shastri, I.M.S., the president of the association, welcomed the visitors and explained to them the prevalence of infectious diseases such as cholera, smallpox, and tuberculosis, and how to prevent them. Dr. Beema Singh of the Ramnad District Medical Association explained in easy Tamil the gist of what Lieutenant-Colonel T. S. Shastri said in English, and elaborated on 'Birth Control' which is very necessary for the working classes.

Lieutenant-Colonel T. S. Shastri, I.M.S., then requested Mr. Ashworth, the manager of the mills, to kindly open the exhibition. Mr. Ashworth, in declaring the exhibition open, said that such exhibitions are very useful and instructive to the masses and encouraged his staff to take interest in their own sanitation, thereby promoting efficiency of work.

This was very much appreciated by the large gathering of about 400 mill workers and school children.

Monthly meeting

The Tinnevely District Medical Association held its monthly meeting on Sunday, 20th December, 1936, at the Government Training School, Koilpatti. Members numbering 25, including two women doctors, were present on the occasion. Seven members of the Ramnad District Medical Association were also present (as guests).

After tea, the meeting began under the presidency of Lieutenant-Colonel T. S. Shastri, I.M.S., at 6 p.m. The secretary read the minutes of the monthly meeting held at headquarters on the 21st November, 1936, which were passed.

The following interesting clinical cases were demonstrated:—

(1) A case of long-standing fæcal fistula, due to unoperated strangulated inguinal hernia.

(2) A case of osteomyelitis, great trochanter, in a boy.

The following specimens were shown:—

(1) A case of dermoid cyst of ovary.

(2) Fibroid uterus (suspicious of malignancy).

The notes on the (1) fæcal fistula and (2) osteomyelitis cases, operated on by Lieutenant-Colonel T. S. Shastry, I.M.S., at the Government Headquarters Hospital, Palamcottah, were read out by Dr. P. S. Srinivasan, L.M.P., sub-assistant surgeon of the hospital.

Dr. Miss A. Lazarus, L.M.P., read out case-notes on (1) ovarian dermoid and (2) fibroid uterus, which were operated on by Lieutenant-Colonel T. S. Shastry, I.M.S., at the Government Women and Children Hospital, Vannarpet.

The above four cases were fully discussed by the members. Then, the president explained in detail the clinical examination, differential diagnosis and operative technique of all the cases. Then he thanked the headmaster of the school for placing the school halls at the disposal of the association for holding the meeting.

He also thanked Dr. T. R. Ramachandran, L.M.P., for the excellent arrangements.

THE PARKES MEMORIAL PRIZE, 1936

MAJOR E. F. W. MACKENZIE, O.B.E., M.C., Royal Army Medical Corps, has been awarded the Parkes Memorial Prize for his investigations into the ammonia-chlorine process of water purification in the field, coupled with research carried out by him in connection with food supplies in India. By this work Major Mackenzie has achieved much in the advancement of military hygiene.

The Parkes Memorial Prize is awarded annually to the officer who is considered by the committee to have done most to promote the advancement of naval or military hygiene by professional work of outstanding merit, and is open to medical officers of the Royal Navy, the Army, and the Indian Army, with the exception of the professors and assistant professors of the Royal Naval Medical College, Greenwich, and of the Royal Army Medical College, London, during their term of office.

(From the *Lancet*, Vol. II, 15th and 22nd August, 1936, pp. 391 and 448)

THE IMPORTANCE OF PROGNOSIS

LEPROSY is not a fatal disease. The patient dies from complications and neglect rather than from the disease itself. It is perhaps because of this non-fatality, and because the patient is afraid that he may be doomed to long years of suffering, perhaps more mental than physical, that he so much fears leprosy. He has heard of, or perhaps seen, lepers in their more repugnant forms. The word 'leper', or its equivalent in other languages, is associated with the last degrees of degradation and abhorrence. In India it is called 'the great disease'. The public and even the medical profession are unaware that leprosy may be a very mild disease, and that even without special treatment many cases recover completely.

Because of all these facts, a reliable prognosis is perhaps of more importance than in most other diseases. In many diseases the infecting organism varies in virulence under certain circumstances, such as repeated and rapid passage from host to host. There is no reliable evidence that the virulence of *B. lepræ* varies in this way. The two important factors to be estimated in making a prognosis in leprosy are the concentration and distribution of the bacilli in the body and the resistance of the patient to the infection.

As in tuberculosis, so in leprosy also, many are infected who never develop the disease. In others there are abortive clinical signs which appear chiefly in the form of macules during some period of debility, and disappear again when the general health is restored. In others again the disease is confined to a single nerve and its branches, the infection being unable to escape either through the epineurium or through the terminal branches in the skin. In some cases two or more nerves are affected in this way, but the disease is not generalized.

LOCALIZED INFECTION

The confining of the infection to one or more nerves is a sign of comparatively high resistance to the

disease. Clinically there are signs of thickening and tenderness of the nerves affected, and local neural signs in the form of sensory, trophic, and vascular changes in the skin, muscles, bones, and joints. In these cases the lesions may remain stationary for a considerable period of months or even years, or active signs may gradually disappear, self-healing taking place. If at any time, while infection still persists, the patient becomes seriously debilitated due to an intercurrent disease or other cause, there is always the danger of exacerbation and widespread generalization throughout the body. In India—and there is reason to believe that the same holds good in many other endemic countries—more than half the patients showing clinical signs of leprosy belong to this resistant class. In them the prognosis is favourable, and it is so in direct proportion to the restriction of nerve involvement. While in a certain number of cases the disease is abortive and self-healing, in many others special treatment is necessary for ultimate recovery. In all, the factor of most importance is the restoration, improvement, and steady maintenance of as high a standard as possible of general health.

GENERAL INFECTION

In contrast to the cases described above are those in which the infection is not confined to the nerves, but spreads through the skin and mucous membranes, invades the lymphatics, and involves the internal organs. This form of leprosy is much more actively progressive. At least to begin with, the clinical signs tend to be less conspicuous than those of the resistant form. For although the concentration of bacilli is greater, the tissue reaction to the bacilli both in the skin and in the nerves is considerably less. The disease is thus frequently able to spread throughout the body without attracting the attention either of the patient or of the physician. Later, as the concentration of bacilli increases enormously, more conspicuous lesions appear in the form of skin thickening and nodulation. This latter is the cutaneous form of leprosy. It is found in patients in whom resistance to the infection is low. In this form the nerves are also invaded—to a greater degree indeed than in nerve leprosy—but, as tissue reaction in the nerves is absent or only slight, the sensory, trophic, and other signs dependent on neural involvement are also comparatively slight.

In this connection it should be stated that leprosy is a disease of exceedingly low toxicity. Its signs and symptoms are due not to toxins set free in the circulation but to the tissue reaction which the presence of *B. lepræ* excites locally. The local response to *B. lepræ* is in direct proportion to the local concentration of *B. lepræ*; but a much more potent factor in determining the cellular reaction is the resistance or immunity of the patient, which varies greatly in different cases.

We have indicated the two chief types of leprosy; the contrast between them is chiefly due to the degree of resistance, which is high in the former or neural type, and low in the latter or cutaneous type. As, however, in many cases the resistance varies considerably from time to time the signs of both types may be present at one time forming the *mixed* type of leprosy.

FACTORS INFLUENCING RESISTANCE

It will be plain from the above that the prognosis depends very largely on the resistance of the patient. There are four main factors which influence the degree of resistance:—

1. Natural resistance to leprosy is strong in healthy adults. Human leprosy has never been transmitted to experimental animals as a progressive disease, and their high resistance is apparently shared by healthy human adults. Also as with most other infectious diseases the degree of natural resistance to leprosy is probably greater in some subjects than in others, apart altogether from the state of their general health. It has been stated by some writers that this natural resistance not only applies to the individual, but also that in areas where leprosy has for a long time been endemic the more susceptible are gradually eliminated, and that thus race immunity is evolved. While this may be argued from the analogy of certain other diseases, there is but little direct evidence in its support.

2. Natural immunity is most markedly influenced by the age factor. In early childhood the resistance to leprosy is very low. Our recent surveys in Calcutta and in the Bankura District of Bengal show that children who have lived in close contact from their earlier days with infectious relatives or servants, in households where special precautions were not taken, seldom escape the disease; and the majority develop the severe infectious cutaneous type of the disease. Other children and adults exposed apparently to the same infection commonly either escape the disease or develop mild non-infectious lesions of the neural type.

Children infected in the first few years of life often show the 'juvenile' type of the disease. Slight depigmented macules with roughening and keratosis of the surface of the skin appear on different parts of the body from time to time, but bacteriological examination of these lesions is generally negative. About the age of puberty these macules may disappear permanently with recovery of the patient, or they may develop and show the cutaneous and infectious type of the disease; much depends upon the general health as the determining factor.

3. Most of those infected after the susceptible age-period—say after the tenth year—escape the severe and infectious type of the disease. If, however, the general health is severely depressed, or is even slightly depressed for a long period, the cutaneous (severe) type of the disease may develop. Such depression of health may be caused by a variety of causes; complicating diseases, dietary errors, pregnancy, etc.

4. Another cause of weakened resistance to leprosy is of a more specific nature—viz, the increase of the infection in the body beyond a certain degree. Thus a vicious circle is produced, the bacillary concentration facilitating the further increase of bacilli and paralysing the mechanism which would arrest that increase.

In contrast to the above is the effect of small infections, which generally tend to increase or supplement the natural resistance. Thus, in patients who have passed the age of increased susceptibility and are in fairly good health, contact even with highly infectious cases may, with or without the appearance of

mild leprosy lesions of the neural type, develop an acquired immunity. Even in healthy young children this specific immunity may be formed, provided that contact is not too frequent and the degree of infection be not too great.

Among healthy adults there tends to be a considerable hiatus between what we term 'resistant' and 'non-resistant' cases. In the former the disease frequently dies out or remains stationary for long periods of years without showing any tendency to increase; in the latter it tends to progress. The hiatus between the resistant and non-resistant cases may be broken down by anything which impairs the general health.

In determining the resistance of the patient we rely chiefly upon the clinical and bacteriological examination. In addition, however, the leprolin test is of considerable value, and the erythrocyte sedimentation test is of great use in estimating the general resistance.

The prognosis may be conveniently divided under three main heads: (1) In infectious contacts (contacts with infectious cases) without signs of the disease, what is the likelihood of leprosy developing? (2) In those in whom leprosy has developed, and definite signs are present, what are the chances of recovery? How long will it take, what are the chances of relapse, and will recovery take place with or without deformities and disablement? (3) How long should treatment be continued after active signs have disappeared, and how long should the patient be kept under observation?

INFECTIOUS CONTACTS

We use this term to indicate those who have been in contact with infectious cases of leprosy but who have not so far shown any signs of leprosy.

The factors which determine the danger of contact are its closeness and duration, the infectiousness of the case, and the age and general health of the person exposed to contagion. Thus a debilitated adult or a young child may occasionally acquire the disease after even short or slight contact with a highly infectious case. Undoubted cases are also known where dwelling in a house vacated by a leper, or use of furniture formerly used by a leper, have been followed by the appearance of leprosy. Fortunately the danger of contracting leprosy in Great Britain is now very slight. Besides those who have recovered from the milder forms of the disease, there are probably about one hundred patients with active leprosy in Great Britain at the present day. With few exceptions these have contracted the disease in our colonies, or in other tropical countries. Some twelve are in a leper home in Essex; the rest live in their own homes. There the simple precautions taken are sufficient to prevent the spread of infection.

Leprosy is far less communicable than tuberculosis. Chiefly for this reason the former disease in an endemic form died out from England centuries ago, while the latter is still prevalent. That is why leprosy is not a notifiable disease, and thus we have no exact figures regarding the few cases that still remain.

In making a prognosis the most important point to be ascertained is the age when contact first took place. If this was within the first few years of life, and especially if there was prolonged and close contact with a highly infectious case, then, even though several years may have passed since then and no signs of the disease have been noticed, it is possible that a generalized infection may have taken place which will show itself sooner or later. If the reaction to leprolin is strong the prognosis is good; if the reaction is negative or weak the prognosis is unfavourable. In such cases careful clinical examination with the aid of a suitable light will often reveal macules which had escaped notice before; or careful and repeated bacteriological examinations of the skin or mucous membrane may show acid-fast bacilli.

In healthy adults who have been in contact with infectious cases and show no signs, the prognosis is as a rule much more favourable. If a considerable period has passed since contact took place then definite

signs of the neural type of leprosy would probably have declared themselves if infection were present in the body, but here too the leprolin test is of value.

In adults who are or who have been in a poor state of health, the danger of the infection developing is much greater. If there is a history of severe or prolonged disease or of other predisposing conditions during the interval since contact took place, if the sedimentation index is high, and if the reaction to leprolin is negative or weak, then a very guarded prognosis is necessary; clinical or bacteriological re-examination of the patient may reveal positive signs sooner or later.

PATIENTS WITH LEPROUS LESIONS

In making a prognosis the important points to ascertain are the degree of infection and the special and general resistance of the patient to the disease. All patients should be divided into resistant and non-resistant groups. It is important to go carefully into the medical history of the patient, especially with regard to predisposing causes; the general appearance, bacteriological examination, and the extent of the lesions may give a clear indication, and here again the leprolin and sedimentation tests should be used.

The following table gives the main distinctions between resistant and non-resistant cases:—

Resistant	Non-resistant
One or only few macules, with anæsthesia to light touch, and with pronounced erythema; thickening and induration of the skin either throughout the lesion or at the margin.	More numerous and widespread and flatter lesions without marked erythematous thickening or induration, the margin merging with the surrounding skin. Erythema less pronounced. Hypo-pigmentation is more noticeable.
Thickening and tenderness of the sensory or mixed nerves connected with the macules.	Nerve thickening as a rule not marked.
Generalized infection of the skin is never present, the disease of the skin being confined to a few macules.	In advanced cases skin involvement may be widespread covering the whole body, with no appearance of macules. While in some of these cases there is noticeable thickening and nodulation, in others it is difficult to recognize the presence of disease on inspection though bacteriological examination shows widespread infection.
Lesions grow slowly or remain stationary for long periods, often for years.	New lesions continually appear and macules grow rapidly in size and coalesce, until almost the whole skin is involved.
Bacteriological examination of the skin shows few or no acid-fast bacilli.	Bacilli are found in lesions of the skin and nasal mucosa in greater or smaller numbers.
There is strong reaction to leprolin.	Reaction to leprolin is absent or very weak.
In resistant cases the prognosis is excellent provided the patient remains in at least moderately good general health. The lesions should disappear under treatment in a comparatively short time (a few weeks to a few months); and the danger of relapse, once all signs of active disease have disappeared from the skin and the nerves, is very small, provided that the patient's general health is maintained.	
In non-resistant cases the prognosis is much more doubtful. If the general health is good, or if under	

suitable treatment it becomes good, and especially if the sedimentation of erythrocytes is slow, then a favourable though guarded prognosis may be given. The period of treatment necessary will, however, be much more prolonged. In many cases of low resistance a definite prognosis should be delayed until there has been time to observe the progress made under general and special treatment. The effective treatment of complicating diseases, along with the carrying out of a strict regime of careful diet, active and suitable exercise, and regular habits, is often found to bring about within a few months, or it may be in one or two years, improvement up to a certain point, after which the patient progresses steadily towards recovery, though several years may be necessary to get rid of all active signs.

RESIDUAL TROPHIC LESIONS

The question of recovery with or without permanent lesions and deformity is an important one for the patient. The earlier treatment is begun and the more carefully it is carried out, the less likelihood is there of the development of trophic lesions of the hands, feet, and face. Carefully planned physical exercise is very important in this connection. Nerve reaction in the ulnar and peroneal nerves, which so commonly results in claw-hand and drop-foot, seldom occurs in patients with firm well-developed muscles. In most cases a certain amount of anæsthesia and, if the larger mixed nerves have been involved, of trophic changes in the small muscles are likely to persist. These should not be mistaken for active signs of the disease.

PERIOD OF TREATMENT AND OBSERVATION

The length of treatment and the period of observation necessary after the cessation of treatment are matters of extreme importance. Treatment is frequently stopped far too soon, and relapse follows causing disappointment to the patient and loss of confidence in the treatment of leprosy.

In non-resistant cases clinical appearances are most deceptive. Lesions will often disappear as a result of complicating diseases, the depression of cellular reaction to *M. lepræ* giving a false appearance of improvement. Bacteriological examination should be carried out thoroughly and repeatedly till the results become negative in smears taken from all parts of the body before the disease is declared quiescent, and it should have remained quiescent for at least two years before it is declared arrested. Thereafter the patient, though he may resume his ordinary social life, should remain under observation for several years; for though bacilli may be absent from the skin and nasal mucosa, they may still remain present in the peripheral nerves. Until careful bacteriological examination is negative on repeated occasions, the patient should observe isolation at least as regards his room, furniture, and eating utensils. There is probably little danger from his travelling in public vehicles, unless he is a highly contagious case; but he should avoid having his meals with others, except at home where special precautions can be easily arranged. He should be specially careful to avoid contact of any sort with young children.

In resistant cases the necessary period of treatment and after-observation is much shorter. In most of them bacteriological examination is negative from the beginning or only very few bacilli can be found in the lesions. In such cases where careful and repeated bacteriological examinations have been consistently negative the criteria of quiescence and arrest must be based chiefly upon clinical examination: (a) lesions are flattened out, so that the finger on passing along the surface from the normal skin to the lesion cannot detect any raised margin, and the skin picked up between finger and thumb feels no thicker than the healthy surrounding skin; (b) thickened nerves lose their tenderness on pressure or percussion, and become reduced to their normal size; (c) no new lesions appear, and the original lesions no longer increase in size; (d) the areas of anæsthesia, though not entirely disappearing, remain stationary in size, neither increasing nor diminishing.

Lastly, in all types of cases and at all stages of the disease the mental outlook and equipment of the patient are of vital importance. The intelligent patient who is full of courage and determination to get better stands a much better chance than the stupid, lazy, or opinionated one. This is true of other diseases, but in none so much as in leprosy, in which the justification for mental depression is so great, and so much depends on the prolonged and persistent efforts of the patient himself.

The Treatment of Asthma

By C. M. WILSON

(From the *Lancet*, Vol. II, 10th October, 1936, p. 872)

At one time a cold in the head infecting both antra left me with asthma although I do not come of asthmatic stock. I have now been free from asthma for some years, but my experience as an asthmatic stretching over some months has influenced my attitude towards treatment. My physicians spent a long time in examination of the chest, but only the smallest fraction of the consultation was devoted to treatment. Moreover they left me convinced that I had asthma for life. A middle-aged doctor contracting asthma is in no need of depressing doctrines, he himself will supply the note of pessimism.

Nothing is known of the asthma diathesis which is the essential factor in the pathogenesis of the disease. If it is due to some change in the chemistry of the blood we know nothing of that change. Accordingly the congenital abnormality at the bottom of the malady remains untreated. The effect of altitude is interesting in this connection, and this effect is seen if the patient goes up in an aeroplane just the same as if he lives in the Alps at a height of four thousand feet, suggesting that it is lowered oxygen tension or some such factor that leads to the biochemical changes which bring freedom to the asthmatic. The vast majority of asthmatics lose their asthma in the Alps, but it soon recurs on returning to lower levels. It is not therefore a very helpful line of treatment. But in the case of asthmatic children, permanent relief often follows a prolonged stay in the Alps. At such places as Montana, Villars, and Chateau d'Oex children can be educated in schools where English is spoken at no greater expense than at a good preparatory school when it is remembered that the child also spends his holidays in Switzerland. In people with the asthmatic diathesis certain stimuli—chemical, reflex, and psychical—lead to bronchial spasm. The chemical stimuli such as the emanations from animals and so forth raise the question whether skin tests are worth doing in an asthmatic. Dramatic results have followed the removal of noxious material or desensitizing the patient to the protein concerned, but skin tests have on the whole proved disappointing. Of the reflex causes of asthma, an overloaded stomach is a proverbial cause of trouble and there are places on the continent where the patient is allowed nothing to eat after 5 p.m.

As far as the nose is concerned, though many claims have been made, the results of treatment are not very encouraging. Everyone will agree that if there is infection of the sinuses it is likely to lead to bronchitis and that an attempt must be made to clear up the infection. If there is pronounced nasal obstruction due to a deviated septum or polypi there is something to be said for the provision of a clear air-passage when other methods of treatment have failed. The touching of the nasal mucous membrane with the cautery under cocaine is perhaps the most hopeful method open to the aural surgeon, especially if the nose appears healthy. But only a fraction of cases respond and relapses are common.

One can hardly exaggerate the importance of the mind in asthma. As a man may go to bed knowing that he has an early train to catch, so an asthmatic retires anticipating a nocturnal attack. For months I myself woke every night at 2 a.m. which could not

be attributed to any organic reason. An asthmatic must be weaned from his habit. Nothing else in the treatment of asthma is of the same importance as the discipline of the mind. The mental processes are familiar to anyone who has suffered from the disease. To those who happily have not learnt these processes by personal experience the letters of Disraeli to Lady Bradford will be instructive. Disraeli thanked God for the gout because he was generally free from asthma when he had gout. But when he was near the end Queen Victoria insisted on a second opinion. Kidd, his doctor, called in Sir Richard Quain, but Quain refused to meet a homœopath, and only consented to do so when it was represented to him that it would be disloyal to do otherwise. Even then he demanded in writing assurances that Kidd was acting under him and that Disraeli was being treated not by homœopathy but by allopathy. With these assurances Quain consulted the Head of the Profession and, receiving the 'All Clear', proceeded with Kidd step by step and arm in arm in hopefulness to hold their first consultation.

In the treatment of the actual attack adrenalin is most useful. The unpleasant palpitations following the hypodermic injection and the possible injurious effects on the blood pressure and arteries are avoided by giving small doses. One or two minims are adequate. Adrenalin can usefully be given as a vapour. Ephedrine has the advantage that it can be taken by mouth and that the effect lasts six or eight hours. The inhalation of fumes from burning such substances as stramonium is liable to irritate the bronchial mucous membrane, so that I never use this method in an attack.

In suitable patients the use of physical exercises in asthma is a more hopeful line of treatment than any medicinal remedies. The difficulty in asthmatic breathing is to empty the lungs which are overdistended. The first object of the exercises is to teach the patient how to do this by using the lower part of his chest and abdominal muscles and by diaphragmatic breathing instead of using only the upper part of the chest. Exercises should be carried out with the assistance of a masseuse who is an expert in remedial exercises. The art of treating an asthmatic is an individual art, but there is one secret common to all successful treatment and this is to teach the patient to discipline his mental processes. The consensus of informed opinion will probably now wish to add another discipline, the control of the respiratory movements.

Cough in Children

By DR. ALAN MONCRIEFF

(From the *Lancet*, Vol. II, 10th October, 1936, p. 871)

THE commonest symptom in outpatient work in a children's department is undoubtedly 'cough', and I have thought it preferable to deal with this complaint rather than with any of the diseases in which it specially occurs. Not only is it the commonest presenting symptom in childhood taken as a whole, but as a rule it is not associated with disease in the chest, so that the average textbook dealing more particularly with disease syndromes does not adequately cover its more usual causes.

Viewed as a modified reflex act, cough can be regarded as always having somewhere a site of origin. I do not propose to deal in detail with the very interesting work which has been done in recent years on the relative sensibility of the various areas, but I must mention that the origin of the cough reflex is much more likely to be in the upper part of the respiratory tract—i.e., above rather than below the bifurcation of the trachea. The simplest way to consider the subject is to follow the respiratory tract down from its upper reaches and thus enumerate the different areas from which a cough may arise. Acute inflammation of the nose and nasopharynx comes first, and it is here that adenoids and infections of the nasal sinuses are of great importance. Pharyngeal coughs and tonsillar coughs

are probably the commonest you find in childhood, and it is well to realize that a cough rather than the complaint of a sore-throat is the presenting symptom in most cases of tonsillitis in the young child. It is just this type of cough which is diagnosed as bronchitis by the mother and often treated as such without medical advice; which, in the case of diphtheritic tonsillitis for example, may be a disastrous course.

The middle ear may strictly be regarded as a branch of the respiratory tract, but I doubt whether a cough ever arises as a result of ear disease alone, although I have been told of an instance where a foreign body in the external auditory meatus did appear to be the cause of cough. Next on the way down comes the larynx, and here the characteristic 'croupy' element generally makes diagnosis easy. In the child most laryngeal coughs are due to a combination of inflammation and spasm, and quite apart from the strict groups of laryngitis and laryngismus there are two conditions to be remembered of importance with a croupy cough. One is the early stage of measles in which the cough is probably due to Koplik's spots on the laryngeal mucosa and the other is retropharyngeal abscess. Arising from the trachea are a group of coughs—harsh, painful, ineffective—which are the end-results of an infection of the nose spreading downwards. Coughs of tracheal origin may also occur with an enlarged thymus or enlarged mediastinal glands. Inflammation of the bronchi may be associated with extraordinarily little cough; usually there is a certain amount of coughing, but it is noticeable that this diminishes as the finer tubes become affected and even more if the inflammatory process reaches the alveoli. Pneumonia, for instance, may be an almost silent disease, and such a serious malady as acute miliary tuberculosis gives rise to little or no cough. In speaking of tuberculosis I would emphasize that this disease as a cause of cough in childhood is comparatively rare.

Still further down, so to speak, comes the pleura, and a short period of irritating cough is a feature of the early dry phase of pleurisy. Of the other forms of cough, which do not appear in this list, whooping-cough is the most important. The diagnosis of this malady by means of the cough plate is becoming perfected, and I have found the sublingual ulcer of very great value, particularly in the early stages. The possibility of a 'stomach cough' is supported by certain experiments, but I think more often the cough and the gastric upsets have a common origin in the catarrhal state of the pharynx. Finally cough may sometimes be a habit spasm.

When the origin of a cough has been correctly diagnosed treatment becomes relatively simple. Clearly for coughs affecting the upper respiratory tract a sedative linctus is indicated in addition to measures dealing with the local infection. A useful prescription is (for a child of one year): tinct. opii camph., oxymel scillæ, and glycerin., ãã 10 minims; water to 60 minims; one teaspoonful as required. If there is evidence of bronchitis some expectorant mixture is usually employed, but I am coming to believe less and less in the value of these drugs. The commonly used tincture of ipecacuanha in doses of 5 to 10 minims is probably largely ineffective, while larger doses may seriously upset a child's digestion. Probably the best clinical measure in bronchitis is to give a copious supply of fluid to keep the bronchial secretion from becoming thick and retained. For the same reason a moist atmosphere is also beneficial, provided it is not allowed to get too warm; it is best obtained by steaming a kettle into the room at intervals while the temperature is not allowed to rise higher than about 65°F. to 70°F. Liniments applied to the chest are probably mostly of value because they lead to the child inhaling a certain amount of the medication vaporized by the warm body.

With recurrent bronchitis in the young child two points should be kept in mind as regards treatment. The first is that asthma often masquerades in this guise; the second, that the atmosphere of many houses

is dry and dusty and may predispose to inflammation of the delicate mucous membrane lining the respiratory passages.

Hypnotic Drugs

By L. I. M. CASTLEDEN, M.D.

(From the *Practitioner*, Vol. CXXXVII, September, 1936, p. 358)

LACK of sleep, or imperfect sleep, is so common a symptom that most practitioners have frequently to treat it whatever their department of medicine may be. This together with the fact that the list of hypnotics is constantly growing both in length and in complexity make it desirable to have some kind of working classification of these drugs from which a suitable one may be chosen and into which new preparations may be fitted as they appear. This article aims at an attempt to produce a simple classification of this kind. At the outset it is well to remember that hypnotic drugs are not the only means available for producing sleep, neither should they be the first remedy to be considered. The normal physiology of sleep is not yet understood, but one of the simplest hypotheses is that put forward by Samson Wright, who states that it may be merely the damping down of the conductivity in the afferent and association paths of the nervous system. Such a conception, whilst probably not the whole truth, is of use to the clinician in that it serves as a reminder of the paths by which sleeplessness may come. There are the extero-ceptive impulses from the external environment of the patient through the surface of the body and the special senses; the proprio-ceptive impulses from the posture of or pressure upon muscles, bones and joints, and from the large group of visceral stimuli amongst which the cardiovascular, gastric and rectal are the most important. In insomnia due to these latter stimuli an alkali or carminative, if there is flatulence, or an enema, if the rectum is loaded, will produce sleep as readily as a hypnotic. Lastly there is the over-activity of the higher centres themselves, the psychic causes of insomnia, one of the commonest of which is the fear that sleep will not be obtainable and of the dire consequences that are likely to ensue. Correction of abnormalities in what may be briefly termed the external and internal environments of the patient may of itself prove to be a hypnotic measure. In spite of this correction, or because it cannot be wholly effected without them, recourse to hypnotic drugs will often be necessary.

THE IDEAL HYPNOTIC

This would have the following properties:—

(1) It would be 'light', that is to say, readily absorbed so that a reliable effect is produced at a regular interval after administration.

(2) It would be rapidly broken down, but not too rapidly, or excreted so that, on the one hand, it would remain in the tissues long enough to ensure a sufficient length of sleep but, on the other hand, not so long as to cause drowsiness the next day or to produce cumulative effects if repeated daily.

(3) It must not produce side actions either unpleasant, such as preliminary excitement and gastric irritation, or dangerous, such as cardiac or respiratory depression.

(4) There must be a sufficient margin of safety between the therapeutic and toxic doses.

(5) The drug must not produce tolerance or habit when administered over long periods.

No drug possesses all these qualities or ever will, but each new hypnotic as it appears is said to be nearer the ideal and there is a real danger that the old, well-tried and reliable remedies are apt to be forgotten in the admiration of the new. Most of the new hypnotics are barbiturates; for this and other reasons they are best kept in a group by themselves. If the opiates are also placed in a separate group, the remainder will be

chiefly composed of the older drugs. These can be considered under the heading of mild and powerful.

THE MILD HYPNOTICS

(1) The analgesics, *phenacetin*, *phenazone*, *amidopyrin*, apart from allowing sleep by removal of a neuralgic or myalgic pain, have a definite mild hypnotic action. Particularly is this so with aspirin, which for most adults and nearly all children is hypnotic.

(2) The alcohols would come into this group, though their use for this purpose, except in the case of elderly debilitated patients who are already habituated to them, should be deprecated. *Amylene hydrate*, an alcohol with more hypnotic action than the rest, has fallen into disuse on account of the preliminary excitement it may induce.

(3) The *bromides*, though really sedatives, are useful in the insomnia of overwork, worry and agitated states. They are rapidly absorbed and more slowly excreted and so may give rise to some depression on the following day. They act by virtue of the bromide ion and so there is nothing to choose between the various bromides at our disposal. The slowness of excretion is due to the fact that the kidney cannot distinguish between chloride and bromide and so both are eliminated in the proportions in which they are dissolved in the tissue fluids, a property which is employed when it is desired to hasten the excretion of bromide. *Sedobrol* and similar proprietary preparations are broths containing sodium bromide in place of sodium chloride.

(4) The urea derivatives (other than the barbiturates) are *carbromalum* (*adalin*) and *bromural*, which, as their names suggest, are bromide urea compounds, and *sedormid*, which has no bromide in it. These substances are mild and light hypnotics, rapid and pleasant in action and without after-effects. *Bromural* has recently been revived by one of the drug houses and is being pushed as a safe hypnotic which is not a barbiturate; these claims are of course true.

(5) The carbonates, examples of which are *urethane* and *hedonal*, are so mild that for some adults they do not seem to be sufficiently potent. They are rapid, safe, have no after-effects and can with advantage be used for children.

THE POWERFUL HYPNOTICS

(1) *Paraldehyde* is well known and much used. It operates quickly, has no unpleasant after-effects, and the sleep it gives lasts several hours, being quiet, refreshing and dreamless. It has no depressant action on the heart or respiration and is of special value in delirium tremens for these reasons and also because it is closely allied, chemically, to alcohol. The only dangers in its use seem to be in cases of acute nephritis or when there is advanced cirrhosis of the liver. Objections to its use are the nasty taste and the odour it gives to the breath. These cannot be overcome but the former can be mitigated considerably by giving the drug as an emulsion in which form it is a much more elegant preparation than when merely added to water: 120 minims of paraldehyde can be emulsified in one ounce of water by the addition of 30 minims of tincture of quillaia. The best flavouring agent is liquorice.

(2) The sulphone group, *sulphonal*, *trional*, has justly become unpopular for the action is uncertain, because such drugs act better in some individuals than in others. Excretion of this group is slow, producing drowsiness the next day and a liability to cumulative effects if repeated doses are given. All members of this series are liable to produce liver and kidney damage and hæmatoporphyrinuria.

(3) The halogen derivatives are some of the most useful sleep-producing drugs available. It used to be taught that they depress the heart in varying degrees and should therefore be used with caution if this organ is feeble, but recent work has shown that they exert no toxic action on the cardiovascular system in therapeutic doses. All are gastric irritants unless given well

diluted. None of them is of any use if insomnia is due to pain. *Chloral hydrate* is typical of this group. It is fairly rapidly absorbed, certain and reliable in action and very useful in simple insomnia or in that due to overwork or worry, especially if combined with bromide. Children take it well. A useful preparation that is not used so much as it might be is syrup of chloral which contains 10.9 grains in 60 minims. Chlorbutol, better known as *chloretone*, has come to be associated with the treatment of sea-sickness and with its properties as a local anæsthetic, but it is a good hypnotic, having the same properties as chloral with less toxicity and less gastric action. *Chloralamide*, another member of this series, is an excellent hypnotic. It is, however, very insoluble, this property probably accounting for its lack of popularity for, unless given in suitable form, absorption and therefore action may be much delayed. There are three ways in which chloralamide may be given:—(a) As a powder, the patient being instructed to dissolve it in a little whiskey and then to add water. If this method is used then the prescription must be for pulv. chloralformamide. Should crystals be dispensed, as they may be if the powder be not specified, the patient, after stirring for some time, will either leave the dose at the bottom of the glass or, if conscientious enough to wash it all down, will spend a wakeful night and sleep most of the following day. (b) Each 60 minims of spiritus vini rect. added to one ounce of water will take up 10 grains of chloralamide in the cold. There are obvious pharmacological objections to such a mixture if a fairly large dose is intended. (c) Tincture of orange, 60 minims, with an equal quantity of simple syrup to each ounce of water will take up 30 grains chloralamide with 30 grains of bromide as well, which is as much as is ever required of this useful mixture. The only way to get the drugs into solution is to dissolve the chloralamide in the tincture with gentle heat and then to add the other ingredients dissolved in the requisite amount of water. Chemists seem to be afraid to heat chloralamide because heat dissociates it, but the temperature at which this happens is 130°F. which is above the boiling point of alcohol.

OPIMUM

Opium and its derivatives are so well known and so widely used as to need only a brief mention. They are all pre-eminently anodyne in action and are therefore the drugs of choice in the insomnia which is dependent upon painful conditions. They are also indicated in the sleeplessness which is associated with heart disease. Apart from these indications they are not good hypnotics. *Nepenthe* is an elegant and useful preparation one-third less strong than the official tincture and without the latter's resinous messiness when diluted. It has the advantage that its name does not suggest an opiate to the uninitiated patient so that it may be added to mixtures containing soluble hypnotics when it is desired to impart some pain-relieving quality to them and later withdrawn. *Omnopon* and *opoidine* are preparations of the total alkaloids of opium which are said to give fewer of the side actions such as nausea and constipation. *Omnopon* is certainly less nauseating to most patients who are affected that way by morphine. Spasmalgin contains a derivative of atropine, papaverine and *omnopon*. *Trivaline* is morphine and cocaine valerianate. *Dilaudid*, a new preparation, is said to have all the pain-relieving properties of morphine without having any other action. This unfortunately is only partly true but appears to be more correct than the similar claims for *omnopon*.

THE BARBITURATES

These drugs are best kept in a class by themselves because they exhibit properties and actions characteristic of a group which contains in itself a practically complete range of hypnotics. They are all substitution products of hypnotics. They are substitution products of malonylurea which is itself the product of the union of malonic acid with urea.

The malonic acid end of malonylurea has two hydrogen atoms either or both of which can be replaced by organic radicles, which may be of the paraffin series, methane, ethane, or propane having one, two, three and so on carbon atoms in an ascending scale, or of the phenolic C_6H_5 group, or again of the acetylene series, e.g., allyl with three carbon atoms. It is obvious from these few examples of possible linkages that a great many permutations and combinations are possible. If, for instance, the two hydrogen atoms are replaced by two ethyl groups (C_2H_5) the compound so formed, di-ethyl malonylurea, is *barbitone* or *veronal* itself. All such substitution products of malonylurea have a hypnotic action and it would seem that the fewer extra carbon atoms that are attached the lighter, i.e., quicker and shorter acting, the hypnotic will be, and, conversely, the more carbon atoms the heavier. A rough rule for guidance is that an ethyl or mythyl group in a barbiturate makes it a light one whilst a phenyl group makes it heavy, and these groups are the most common ones to find, in association with others, so that by looking at the proper chemical name of the drug, which is always printed somewhere on the package or in the literature, usually in microscopic letters, some idea can be obtained of its probable action. Examples of this are *soneryl*, a useful light hypnotic which is butyl-ethyl-malonylurea, whilst *pheno-barbitone* is *luminal*, so heavy, i.e., long and slow in action, as to be almost useless as a hypnotic but invaluable for other purposes because of these very properties.

Some barbiturates are soluble but most are not. If the sodium salt of any of their compounds is made it becomes soluble and therefore has its rate of action accelerated because solubility increases both absorption and excretion. An excellent example of this is *evipan* which has two methyl groups and which is rapid in taking effect and transitory in the drowsiness it produces. It is applicable to those patients who wake at 3 or 4 a.m. and cannot get to sleep again. Four grains by the mouth will produce three or four hours more sleep and the effects of the drug will be gone by the time the patient wakes again. *Evipan-sodium*, on the other hand, is so rapidly diffusible on account of the increased solubility that when injected into a vein its effects are over in about twenty minutes. There are about 168 barbiturates that can be used in medicine and it is possible in so short an article to mention only a few of them. Some have been dealt with as examples of the common structure, others in frequent use are *hebaral-sodium*, the soluble sodium compound of hexyl-ethyl-malonylurea, which is light, efficient and reliable, giving no heaviness the next day. It is an excellent preparation for bedtime use. Others are *dial*, which though light is not so mild a drug as it is popularly supposed to be, *barbitone* itself and its sodium salt *medinal*, *phanodorm*, *pernocton*, and so on through the series to the really heavy members, such as *luminal*, *luminal-sodium* and *prominal*. Certain barbiturates have found a special use in inducing sleep before anaesthesia, *nembutal* being the best known example. It is said that *hebaral-sodium* is useful in this respect and does not cause the excitement not seldom seen after *nembutal*, and that *amytal-sodium* is particularly indicated for premedication in children. This last drug has a special indication in that it may be given by intramuscular injection of an aqueous solution of three grains to calm the almost maniacal excitement sometimes seen in cases of exophthalmic goitre.

Idiosyncrasy to barbiturates is said to occur in 3 per cent of people, and toxic effects may arise from the administration of quite small doses. These may take many curious forms, a few of the commonest being:—

- (1) In the skin. (a) Urticarial weals. (b) Bullae. (c) Morbilliform or scarlatiniform maculo-papular erythema. (2) Alimentary. (a) Anorexia. (b) Nausea. (c) Epigastric pain. (d) Diarrhoea. (3) Nervous. (a) Defects of attention and memory, hence their use as basal narcotics, and hence, also, their danger if patients are administering the doses themselves. (b) Lassitude, fatigue and backache. (c) Confusion,

delusions and hallucinations. (d) Diplopia, nystagmus, ataxia and even coma. (4) Most barbiturates are cardiac depressants of more or less serious nature, and all cause some fall of blood pressure.

An interesting recent development is that by joining the barbiturate radicle to a metallic base, instead of to sodium, its toxicity and depressant action is diminished. *Calcium phanodorm* has been made, and more of such compounds will be produced in the near future. This detoxicating effect is not limited to this group of drugs. *Calcium aspirin*, for instance, is said to be less toxic, though no less analgesic, than plain aspirin.

In spite of severe criticism of their administration the malonylureas have established themselves as useful and reliable hypnotics, as reasonably safe as most potent medicines if wisely used, and out of the controversy that has raged around them certain rules for their administration have emerged:—

- (1) Obese or debilitated patients or those with liver or kidney disease tolerate them badly. (2) Patients with arteriosclerosis, myocardial disease or very low blood-pressure react badly to the shorter acting drugs. (3) Never repeat, for hypnotic purposes, a dose of a barbiturate. (4) Never mix barbiturates. (5) Never give them before, with, or after an opiate. To which excellent rule there is an equally excellent exception, namely, that *medinal* and *nembutal* go very well together. (6) They are better not prescribed in tablet form but in a cachet, as a powder, or best of all in solution. Substitution or reduction of the dose is then possible, which it may not be if the patient has become habituated to a trade-marked tablet.

MIXTURES

Hypnotic drugs are good examples of synergism and for this reason many blendings of them have become traditional, such as pot. brom. and chloral, and all practitioners discover favourite mixtures of their own. In their search for a sleep-producing drug, with pain-relieving qualities, which is not an opium-derivative, the drug houses have put many proprietary preparations on the market which are mixtures, usually in tablet form. *Allonal*, *cibalgin*, *veramon* are examples of a few. Most of them are mixtures of amidopyrin plus a barbiturate, despite the fact that recent work has demonstrated the danger of amidopyrin. There is usually too little analgesic in one tablet and too much barbiturate in two; it is better therefore, if desired, to use such a preparation to prescribe a personally-tested mixture of analgesic and hypnotic.

In the fact that the form in which they are given and that the time of their administration may effect their action, the hypnotics are no exception to other drugs. Solution accelerates their action as does administration at a time when the stomach is empty. It is common to hear patients complain that a preparation upon which reliance can be placed has failed to act when in reality what has happened is that it was taken immediately after a late and heavy meal. For similar reasons if the drug is given in a solid form, particularly as a tablet, the patient should be instructed to take a good draught of water, and not merely sufficient to wash it down.

Asthma: Immunological Mechanism, Diagnosis, and Treatment, with Special Reference to Vaccine Therapy

By D. HARLEY, B.Sc., M.B.

(From the *Lancet*, Vol. II, 15th August, 1936, p. 367)

It is generally accepted that the asthma syndrome is an expression of a state of abnormal sensitivity or increased reaction (allergy) of the body to certain foreign substances, most of which are quite harmless to normal individuals. To take an extreme case; reclining in an arm-chair padded with horsehair causes an attack of asthma in a 'horse-sensitive' asthmatic;

pricking the patient's skin with a needle which has been dipped in an extract of horsehair produces a violent local reaction; the injection of minute amounts of the extract causes severe asthma; the intravenous injection of a few *minims* of horse serum in such a case has been known to kill.

The evolution of the asthmatic state can be divided into three parts:—

1. *Predisposition* of the individual to become hypersensitive. This is commonly inherited but may be acquired. The exact nature of this immunological or biochemical kink is unknown.

2. *Development of hypersensitivity* to one or more of a wide variety of foreign substances. Contact with the offending substances then results in the violent reactions characteristic of the hypersensitive state. Though hypersensitiveness is developed commonly to substances with which the person came into close and repeated contact before the commencement of the asthma, this is by no means a constant feature and the capriciousness of the selection of sensitizing substances is well known. When the hypersensitive state is first developed the specificity of the reactions is usually very definite, the horse-sensitive asthmatic reacting to the hair and dandruff of horses but not to that of dogs or cattle. More commonly the sensitivity is multiple but specificity is still a prominent feature. After a time the asthmatic tends to have his attacks precipitated by one or more of a wide variety of non-specific factors unrelated to the primary exciting cause.

3. *Secondary non-specific factors*.—These include nearly all possible forms of minor trauma—toxic and psychic, direct and reflex, dietetic indiscretions, etc. It has been suggested that these act by lowering the 'tolerance' of the asthmatic to the primary specific exciting causes, so enabling the latter to provoke an attack in even more minute amounts than usually required.

IMMUNOLOGICAL MECHANISM

(a) *Hypersensitivity to non-bacterial products*.—These include inhalants (animal dandruffs, pollens, face powder, house dust, feathers) acting directly on the lungs, and ingested and injected substances (foods, drugs, sera) which reach the lung tissue *via* the blood stream. The active principles in these substances are variously designated *idiotoxins* (Freeman), *allergens*, and *atopens*. When the specific idiotoxins are brought into contact with the tissues of the asthmatic the characteristic reactions of the hypersensitive state are produced; the pathological basis of these reactions is spasm of smooth muscle and increased permeability of blood capillaries; thus urticaria is produced in the skin (this is utilized in the well-known diagnostic skin tests), asthma in the lungs, paroxysmal rhinorrhœa in the nose, etc. The injection of hypersensitive serum into the skin of a normal individual renders the latter hypersensitive locally so that subsequent contact with the specific idiotoxin results in the formation of an urticarial weal. When such a passively sensitized area of skin is acted upon by the specific idiotoxin, in sufficient quantity to elicit the maximum reaction, the site becomes desensitized—*i.e.*, does not react to further treatment with idiotoxin. Passive transfer of sensitivity is due to the presence in the sensitizing serum of special antibodies, the *atopic reagins*, *allergins*, or, more fittingly, *idioceptors*. When idioceptor is attached to the tissue cells the latter are rendered hypersensitive. The desensitization of patients by repeated injections of suitable doses of specific idiotoxin is the result of inactivation of idioceptor as shown by the abolition of the skin sensitivity.

(b) *Hypersensitivity to bacteria and their products*.—One is impressed by the large number of asthmatics presenting themselves for investigation and treatment in whom the asthma first appeared after or is associated with some infective process, often comparatively mild infections of the respiratory tract. Many of these

cases give negative or only very feeble skin reactions to inhalant and ingestant idiotoxins but bacteriological examination almost always reveals marked qualitative or quantitative abnormalities. The excellent results of vaccine therapy in these cases support the hypothesis that the relationship between the bacteria and the asthma is one of cause and effect. Such hypersensitivity to bacteria however is of a different character to the hypersensitivity to non-bacterial substances discussed above. In the latter skin reactions are of the immediate type, consisting of an urticarial weal with erythema, fully developed in 15 minutes or less, and passive transfer of sensitivity by injection of serum can be regularly accomplished. Though immediate skin reactions to bacterial vaccines have been occasionally reported, the common type is a delayed reaction, essentially inflammatory in nature, which takes 24 hours or more to develop, and passive transfer by the injection of serum is not obtained.

Bacterial vaccine skin tests in the diagnosis and treatment of bacterial-sensitization-asthma have been widely used in recent years, especially by clinicians in America. The usual method is to prepare vaccines of the bacteria of the sputum, etc., and test the patient's skin reactions to them. Those which produce reactions are employed for therapeutic purposes. Unfortunately these vaccine skin tests have proved unsatisfactory as it has been found that non-asthmatic individuals often give similar reactions to the vaccines, and also that vaccines of the normal intestinal Gram-negative bacilli often cause bigger reactions in the skin of the asthmatic than do the infecting organisms from the sputum (Rackemann and Graham, Benson, etc.). Experimental investigations (Harley) indicate that the delayed skin reaction is due to an increased sensitivity of the skin cells to the somatic nucleoprotein of the intact bacteria. This type of hypersensitiveness, or allergy as it is commonly called, is produced regularly in man and animals by natural and experimental infections; for example, the convalescent pneumonia patient gives the delayed skin reaction to pneumococcal nucleoprotein (Tillett and Francis), and it is well known that the majority of normal individuals react in the same way to *B. coli* vaccine. The presence of such bacterial allergy in asthmatics therefore is not in itself conclusive evidence that the particular organism producing the biggest reaction is the one responsible for the asthma. At present we have to rely on the clinical history, the absence of skin reactions to non-bacterial idiotoxins, and the bacteriological examination, to guide us in the diagnosis and vaccine treatment of 'bacterial-sensitization-asthma'.

TYPES OF ASTHMA

Clinically, the two main types of asthma discussed above may occur separately or together, with varying predominance of one or other. The following classification is not claimed to be a complete one, but it serves as a guide to the treatment of asthma from the immunological standpoint:—

1. Hypersensitivity to non-bacterial substances.
2. Ditto, plus secondary infections or toxæmias.
3. Bacterial asthma.
4. Ditto, plus secondary non-bacterial sensitizations.

Type 1.—The sensitivities may be single or multiple. Single sensitizations are rather uncommon and the diagnosis is usually readily established from the history and skin tests. Multiple sensitivity is the general rule, though one sensitization may predominate clinically. As the type becomes chronic the sensitivities tend to become more multiple and less distinct, and the constant trauma to the mucous membrane of the respiratory tract encourages the entry of infections to complicate the picture (*type 2*). Alternatively, an infection may convert a subclinical sensitization into an actual one, by lowering the tolerance of the mucous membrane to the specific idiotoxins. The same effect may also take place indirectly—*e.g.*, toxins from a distant focus of infection reaching the lungs *via* the blood stream.

Type 3.—The asthma results from an infection of the respiratory tract. In the case of nasopharyngeal infections, etc., the asthma is often 'reflex'. The history, bacteriological findings, and the absence of skin reactions to non-bacterial substances establish the diagnosis. The lowering of the vitality of the mucous membrane by the infection may encourage the development of minor degrees of sensitivity to non-bacterial substances of the inhalant type, usually resulting in multiple weak skin reactions (*type 4*). Bacteriological examination reveals the primary cause.

IMMUNOLOGICAL INVESTIGATION OF ASTHMA PATIENTS

Skin tests.—The method of testing employed at the St. Mary's Hospital asthma clinic is the 'prick' method (Freeman; Harley).

A drop of the extract to be tested is placed on the skin of the forearm or thigh and the latter lightly pricked once with a hypodermic needle through the drop at right angles to the surface. The drop is then gently wiped off with a pledget of cotton-wool. A positive reaction consists of an urticarial weal with surrounding erythema about the site of the puncture, and is fully developed in 10 to 15 minutes. Control tests are performed with normal carbol-saline. Though much stronger extracts are necessary to elicit reactions by the prick than by the intradermal and scratch methods of skin testing, the prick technique is more exact, and as the amount of trauma inflicted on the skin is much less with this method, doubtful and pseudo-reactions are less frequent.

The rapidity and accuracy with which a patient can be tested with a considerable number of extracts make the prick test the best routine method for the clinic.

Bacteriological examination.—This includes (a) routine blood-agar plate cultures of swabs of tonsils, nasopharynx, and sputum; (b) special examination of faeces, urine, cervix, and other possible foci of infection, if there is any suggestion of an underlying toxæmia, as in cases with feeble skin reactions and normal respiratory tract flora. Tellurite media and anaerobic cultures of the faeces are frequently valuable for the isolation of pathogenic streptococci. In the absence of any obvious pathogens, auto-hæmocultures (pathogen-selective-cultures), which utilize the *in vitro* bactericidal action of the patient's own blood on organisms to which he is immune and allow the growth of pathogenic organisms, often indicate the source of the trouble. Subcultures are made of the predominating pathogenic organisms for vaccine preparation.

TREATMENT

We are not concerned here with the palliative or symptomatic treatment of asthma, the correction of the 'secondary non-specific factors' discussed at the beginning of this paper, or the surgical aspects of focal sepsis, but rather with the treatment of the underlying cause from the immunological standpoint. The success of this type of therapy depends on the accurate diagnosis of the type of immunological mechanism involved in the individual case.

Type 1 cases.—If the sensitivity is to a single substance or to a small number of substances which can be removed readily from the patient's surroundings or diet, *specific avoidance* gives excellent results. Specific desensitization is indicated if specific avoidance is impossible or impracticable; the results in selected cases are highly satisfactory.

Type 2 cases, with multiple sensitivities and infections or toxæmias, usually respond best to vaccine therapy, with or without the above measures.

Types 3 and 4.—The rational treatment is vaccine therapy. Whether a stock or autogenous vaccine is employed, the commencing dose should not be more than 1 million organisms subcutaneously. The dose is repeated at 5- to 7-day intervals, and is cautiously increased till satisfactory results are obtained. After a few months of weekly injections, the interval between doses is gradually increased to one month. The optimal dosage and the length of treatment

required vary greatly, but it is usually advisable to repeat the maximum dose at monthly intervals for at least six months to a year. When there is evidence of chronic bronchitis or frequent winter colds a short course of prophylactic injections each autumn is recommended.

CONCLUSION

The tendency of the advanced allergist to consider all asthmatics in terms of skin reactions to non-bacterial substances, and to institute treatment accordingly, produces brilliant cures in certain cases (*type 1*), but leads to disappointing results where the primary cause is bacterial. I feel this is due partly to the use of the intradermal method of skin testing which frequently produces 'false positive' reactions (that are liable to be misinterpreted by the enthusiast) in the absence of the corresponding *clinical* sensitivities, and to the failure to make a routine bacteriological examination of all patients in whom the skin reactions are multiple and indistinct.

Nutrition in Health and Disease

By SIR ROBERT McCARRISON, C.I.E., M.D., D.Sc.,
LL.D., F.R.C.P. (Oxford)

MAJOR-GENERAL, I.M.S. (Retd.)

(From the *British Medical Journal*, Vol. II,
26th September, 1936, p. 611)

THIS is an historic occasion. The inauguration of the *Section of Nutrition* is the recognition by the Association that the science of nutrition is an integral part of medicine. Last among the sections, it is not the least; indeed, the day is not far distant when, instead of one morning being devoted to its work, it will rank with the section of medicine as a three-day fixture. For with the rapid increase in knowledge it becomes more and more apparent that the science of nutrition is the foundation of a more rational medicine. It is to be hoped that on future occasions the work of this section will not be limited to physiological, biochemical, pathological, and medical aspects of the subject, but that it will include those that are veterinary and agricultural.

Although young in years the newer knowledge of nutrition has already established contacts with, indeed embraces in its compass, every branch of our profession. It may, therefore, serve as a fitting introduction to to-day's discussion to indicate, though without aiming at completeness, what these contacts are; taking the nineteen other sections, into which the clinical and scientific work of the annual meeting is divided, as the basis of this survey.

First, then, in regard to *Medicine*, which heads the list of the sections, and with which *Public Medicine* and *Diseases of Children* may be included. What contacts has the science of nutrition established with medicine? This question can best be answered by defining 'medicine' and by defining 'nutrition'. For the first definition we may look to a lay, or non-professional, dictionary to find what the public expects of medicine. There it is defined as 'the science or art of the prevention, treatment, and cure of disease'; not merely 'any substance given for the cure of disease'; not merely 'the science of the treatment of disease'; not merely 'that branch of the healing art dealing with internal disease'. It is significant that in this definition prevention takes precedence of treatment and cure. Medicine is, in short, the science and art of maintaining health.

DEFINITION

And what is 'nutrition'? It is a fundamental function on which the condition of the body—that is to say, health—depends. It is not merely 'food' nor 'that which nourishes', as some lay dictionaries define it. Food is the instrument of nourishment; nutrition is the act of using it—the series of co-ordinated processes whereby the nourishment of the body is effected. It consists in the taking-in and assimilation through

chemical changes—metabolism—of materials with which the tissues of the body are built up, their waste repaired, and their deterioration prevented; by which the processes of the body are regulated and co-ordinated, from which energy is liberated for the internal and external work of the body, and from which heat is generated for the maintenance of its temperature. A primary purpose of the function of nutrition is, thus, to establish and to sustain the structure and function of all organs and parts of the body: to keep, in short, the mechanism of the body in perfect running order. And since health, at its best—for it is a variable state of being—is that condition of body in which all its organs and parts are sound and perform their functions duly, easily, and satisfactorily, it follows that a primary purpose of the function of nutrition is to prevent, so far as its limitations permit, that disturbance or impairment of structure or function of organs or parts of the body which is disease. This, then, is the relation of nutrition to health and disease—the subject of our discussion to-day—the answer to the question: What contacts has nutrition established with medicine?

The older knowledge of nutrition showed the fundamental relations of the energy-yielding constituents of food to vital activities. It showed, also, the importance of the protein factor in nutrition. But it is only within recent years that the equally important relations of certain food-essentials—notably, mineral elements and vitamins—to the structural and functional efficiency of the mechanism of the body have received their due meed of attention. The study of these relations has led to a new conception of causes and origins of disease: a conception which may be summed up in the sequence—faulty food, faulty nutrition, faulty function, faulty structure, faulty health—disease. It is with this newer knowledge of nutrition, and not with the energy requirements of the body, that we are concerned to-day.

FACTORS AFFECTING NUTRITION

Nutrition, as we all know, depends on a number of factors: the constitution of the food, the adequate oxygenation of the blood and tissues, the efficiency of the processes—digestion, absorption, assimilation, circulation, excretion—involved in this function, proper exercise of the body, rest and sleep, freedom from worry and emotional excitement, general hygiene, sunlight, and inherited characters. Chief among these is food of a constitution that provides all the elements and complexes needed for normal nutrition. Moreover, the lack or insufficient supply of one or more of these essentials, or their disproportion one to another, may be the determining cause of some of the other factors that adversely affect the function of nutrition, thus creating a vicious circle. Imperfect oxygenation of the blood and tissues may, for instance, be the outcome of specific food faults. Restlessness and excitement may be consequences of faulty feeding. Food of improper constitution may be the cause of impairment of any of the processes involved in nutrition. Defects in diet may enhance the harmful effects of want of sunlight. Food is thus the greatest of all factors on which the efficiency of the function of nutrition depends. It is the foundation of health; chief amongst the armaments of medicine against disease. 'There may', as Holt aptly expresses it, 'be normal nutrition without normal health, but there cannot be normal health without normal nutrition'.

Here the question arises: what are the materials wherewith the function of nutrition is effected and whence are they derived? They are, so far as is at present known, oxygen, water, and the digestion products of proteins—fats, carbohydrates, mineral elements, and vitamins. There may be others, probably there are. So we are on surer ground when we consider the food-stuffs which, when properly combined in the diet, are known to ensure perfect nutrition and a high grade of physical efficiency and health in human beings. These foodstuffs are: (1) A good whole cereal grain or mixture of whole cereal grains or a good wholemeal bread. (2) Milk and the products of milk—butter, cheese,

curds, buttermilk. (3) Egg. (4) Green leaf vegetables. (5) Rootts, etc. (6) Legumes. (7) Fru That these provide all elements and complexes, known and unknown, needed for normal nutrition is evident from the fact that they are the ingredients of the national diets of certain races of northern India whose physique and health, when they make use of their national diets in their entirety, are unsurpassed by any other race of mankind. Further, albino rats, when fed on a diet made up of these ingredients, can be maintained in perfect health. Most of these foodstuffs are nowadays classed as 'protective foods'—a discovery made centuries ago by the races referred to, and of which the newer knowledge of nutrition has revealed the importance. If food be the foundation of health, these foodstuffs are its foundation-stones. Using them aright there is little need to concern ourselves too closely with the precise amounts of this or that chemical ingredient of food that may be necessary for normal nutrition. These foodstuffs provide them all and in due amount and proportion one to another. There is, however, this proviso, that they must be produced on soils which are not themselves depleted of essential plant nutrients or of substances, such as iodine, needed for the normal nutrition of man and animals and conveyed to them by plants. 'Les plantes sont les enfants de la terre, de l'air, et du soleil'; and we, in common with other animals, are the offspring of the plants.

Here it may be remarked that important as properly constituted food is at every period of life, it is at no period so important as during infancy and childhood; for then it is that the body is being built, then that defects in its structure and efficiency are so readily established, defects that are at the root of many of the diseases to which man is erroneously supposed to be heir.

BACTERIOLOGY AND PATHOLOGY

So much, then, for Medicine; now as to the contacts of nutrition with bacteriology and pathology. First, as regards the relation of nutrition to resistance to infection. Long long ago, Clausen submitted the available evidence on this question to critical analysis. His general conclusions were as follows:—

'Resistance to infection may be greatly reduced by deficient diet. A deficiency in the diet of vitamin A or of vitamin C appears quite definitely to lower resistance to infection. In certain cases a lack of the vitamin-B complex may also do the same thing. A lack of vitamin D (*per se*) cannot be said to have a proven effect in lowering resistance (such lowering when it occurs is usually due to associated deficiency of vitamin A). It seems probable that the existence of a partial deficiency (of vitamins) may result in loss of resistance to infection.'

Under 'deficient diet', as mentioned in these conclusions, there are to be included deficiency of protein and deficiency of certain mineral elements, notably calcium.

The contacts of nutrition with pathology may best be illustrated by the effects of faulty nutrition on the digestive and endocrine systems: the former a highly specialized mechanism designed for the nourishment of the body; the latter a highly specialized mechanism designed for the control and co-ordination of the round of chemical changes (metabolism) on which nutrition depends.

GASTRO-INTESTINAL TRACT

The discovery of the effects of deficient and ill-balanced food on the tract is 'one of the most significant the rôle of nutrition in preventive discovery was made by feeding monkeys on diets having a number of faults—poverty of vitamins and mineral elements and excessive richness in carbohydrates: faults common in human dietaries. 'Deficient foods are in practice usually ill-balanced foods, and the effects of avitaminosis are bound up with maladjustments both in quality and quantity of other essential requisites of the food'. The health of the gastro-intestinal tract depends

on the adequate provision in the diet of water, proteins, mineral elements, and vitamins. It is unnecessary to enlarge on the functions of water relative to digestive processes. In regard to proteins it is enough to say that they and their contained amino-acids are the source from which hydrolytic enzymes concerned in digestion are derived and from which catalytic agents (glutathione, thyroxine, adrenaline, and insulin) are elaborated. As to mineral elements it needs but to recall that they enter into the composition of all cells, including those of this tract, that they control the permeability of cell membranes, the normal contractility of muscles, and the excitability of nerves, including those of this tract, and, that some enter into the composition of the digestive juices. Their adequate provision is therefore of the first importance to the efficient performance of the functions of the stomach and intestines. Vitamins of the A, B, and C classes have all a profound relation to the structural and functional efficiency of the alimentary tract. Witness the effect of deficiency of vitamin B₁ in impairing the motility of the stomach, with consequent loss of appetite. Witness its effect in impairing gastric secretion and the normal rate of passage of the intestinal residues. Witness the effects of deficiency of vitamin B₂ on the health of the lining membrane of the tract. Witness that of vitamin-A deficiency in favouring infection of it, an effect which it shares in common with deficiency of vitamin-C and of the vitamin-B complex. Witness the congestive, hæmorrhagic and ulcerative lesions produced in it by vitamin-C deficiency. Witness the experimental production by these means in animals of such lesions as gastric dilatation, gastritis, peptic ulcer, enteritis, and colitis. Witness the incidence of gastro-intestinal disease, amounting to 25 per cent of all ailments, amongst insured persons in this country whose diets have so often faults of this character.

DIET AND ENDOCRINES

Consider the effects of faulty food on the endocrine glands: the sensitivity of the adrenals to deficiency of vitamins B and C; the sensitivity of the thyroid to deficiency of iodine, of certain vitamins, and of protein, and its reaction to certain excesses in the food, as of fats and calcium; the atrophic changes in the pancreas brought about by carbohydrate-rich and vitamin-poor diets; the functional impairment of the reproductive due to certain food deficiencies. Food deficiencies, as I pointed out many years ago, derange both the normal production of hormones and the functional perfection of sympathetic nervous control. Consequently, organs such as those of the digestive system are deprived of the full advantage of that efficient regulation and correlation which normally they would derive from healthy endocrine action. Fifteen years ago I wrote as follows: 'Especially do I direct attention to the effects of food deficiency on the digestive organs and on those endocrine organs concerned in the regulation of metabolic processes. These effects provide the pathological basis for attaching to food deficiencies a prominent ætiological significance in regard to that great mass of ill-defined gastro-intestinal disorders and vague ill-health which throngs clinics at the present day, and concerning which we have hitherto known little or nothing'. I repeat this passage with the greater emphasis to-day, since the intervening years have provided abundant confirmation of its truth.

OBSTETRICS AND GYNÆCOLOGY

Contacts of nutrition with obstetrics and gynæcology are many. It will suffice to mention some of them: the impediments which the effects of rickets and osteomalacia may present to parturition; the relations of food, in particular of fats, mineral elements, and vitamins, to fertility, pregnancy, and lactation; the rôle of linoleic acid (sometimes called vitamin F) in favouring fertility; the probable effect of fat in facilitating the transference of vitamin A through the placenta to the fœtus; the need for an abundant supply of

vitamins A, B, and C and of calcium, phosphorus, magnesium, and iron to pregnant and lactating women, and their need for adequate supplies of vitamins D and E and of iodine; the rôle of vitamin E in preventing habitual abortion; the effects of vitamin-A deficiency on the reproductive tract—vaginal cornification, prolonged gestation, difficult parturition, uterine bleeding, variations in size of the placenta, tissue necrosis of the uterine wall—effects which in their turn may favour endogenous or exogenous infection. It is true that these effects have so far been observed only in rats, but is well within the bounds of possibility that they may result in women from similar dietetic causes. It is significant that they occur in rats kept at levels of vitamin-A deficiency insufficient to cause xerophthalmia. All these observations indicate the necessity for the proper feeding of prospective mothers, and of pregnant and nursing women: a necessity as much in the interests of the child as of the mother.

SURGERY AND ANATOMY

In regard to surgery little need be said except that the need for it will lessen, certainly in the treatment of internal diseases, when the people learn to feed themselves properly and have the means to do so, and when the profession learns to lead them along the healthful ways of nutrition. The triumphs of surgery—and who would wish to minimize them?—are often the defeats of medicine. But as surgery was resuscitated, not so very long ago, by the application of the principles of antiseptics, so will medicine, now so dependent on surgery, be resuscitated by the application of the principles of nutrition. The relation of nutrition to surgical results, to the healing of wounds, to the mending of fractures, and to chronic bone and joint diseases needs no emphasis.

Coming now to anatomy: what relation has nutrition to this? Clearly an important one, especially in regard to the minute structure of the tissues of the body. 'For however necessary a knowledge of normal structure of organs and parts of the body may be, it is not less necessary to possess a knowledge of the structural changes induced in them by so fundamental a factor as faulty food'.

PHYSIOLOGY

Physiology and biochemistry are so closely interwoven with the science of nutrition that they may be said to be departments of it. Their contacts with it are obvious. To biochemistry has fallen the task of isolating the vitamins; a task it is fulfilling with conspicuous success. There is, however, the risk that in the maze of vitamin and biochemical literature the practitioner of medicine may lose sight of the simple fact that all that the body needs for perfect nutrition is provided in the relatively few foodstuffs already mentioned, if these be consumed in proper quantity and in the form in which nature provides them. Then the questions as to what vitamins, what minerals, what other substances, and how much of them are needed by the body are answered for him and more certainly than by biochemistry.

NOMENCLATURE

Here some reference may be made to the nomenclature of the vitamins. These are still spoken of as 'accessory food factors', as 'anti-this' or 'anti-that' deficiency. The time has come to disencumber them of these limiting descriptive terms. For they are not 'accessories' but essentials, in no way subordinate to the other principles of food. They are substances indispensable to nutrition at every stage in its processes from appetite and the ingestion of food to the evacuation from the body of its waste products; substances without a sufficiency of which normal structure and normal function of organs or parts of the body cannot be maintained; substances as essential to the mechanism of the body as oil is to the mechanism of the car. It is true that they oppose the occurrence of this or that 'deficiency disease'—a term that has also outgrown its usefulness—but they have, as I pointed out many

years ago, much else to do besides the prevention of these maladies, and this much else is their greater function. The main objection to the continued use of these terms is the impression they convey that because there is no xerophthalmia there can be no vitamin-A insufficiency, or because there is no beri-beri there can be no vitamin-B insufficiency, and so on through the list of 'antis'. It is the insufficiency, the inadequate ingestion, absorption, or utilization of the vitamins rather than their complete absence from the diet (an exceedingly rare event, even in the case of beri-beri) that is of such importance in the practice of medicine. These terms were well enough as props to a dawning understanding of the rôle of the vitamins in nutrition. But now that the edifice of knowledge has come to rest on a sure foundation these props are no longer needed.

PSYCHOLOGY AND NEUROLOGY

Nutrition has a close concern for psychological medicine and neurology.

'The rapid growth of the brain and the development of the nervous system render the growing child peculiarly susceptible to nervous disturbances, whenever conditions of life are such as to interfere with normal nutrition. Most of the neuroses of childhood depend entirely upon disorders of nutrition. The headaches, insomnia, disturbed sleep, chorea, habit-spasm, hysterical manifestations and a multitude of others are relieved only by correcting the faulty diet and habits which are the basis of the disturbed nutrition'.—Holt.

The relation of nutrition to intelligence and backwardness in schoolchildren, the mental disorders in pellagra, the interdependence of physical and mental conditions are other examples of the contacts of nutrition with psychological medicine.

It is now definitely known that deficiency of vitamins A, B₁, and B₂ has important relations to the development and health of the nervous system. A striking example of this truth is that afforded by the tissue-culture work carried out at the Nutrition Research Laboratories, Coonoor. There it was found that embryonic nerve tissue failed to grow normally in the plasma of animals deprived either of vitamin A or of vitamin B. Among the effects on the nervous system of vitamin deficiencies are non-inflammatory peripheral neuritis, degenerative changes in the brachial plexus, sciatic nerves, sensory tracts in the periphery of the spinal cord, posterior columns and posterior nerve roots, Gasserian ganglion, and less commonly in anterior nerve roots and vagus. The nerve changes often present in pellagra in man, as well as the association of vitamin-B₂ deficiency with beri-beri, with some cases of neuritis in pregnancy and, possibly, with alcoholic neuritis, are familiar examples of the contacts of nutrition with neurology.

In the field of ophthalmology the relation of night-blindness—of which there appear to be minor degrees more common in Western countries than was formerly supposed—xerophthalmia, and keratomalacia, to deficiency of vitamin A, is now well established. In connection with it, it may be recalled that the changes brought about by it in the conjunctiva appear to confer pathogenic characters upon otherwise harmless saprophytes present thereon; changes in the soil seem to alter the characters of the seed.

ORTHOPÆDICS AND RADIOLOGY

Orthopædics has contacts with nutritions that are exemplified in the results of rickets and osteomalacia. The fragility of bones, spinal curvature, displacement of vertebrae, diseases of joints, slow and imperfect mending of fractures, all caused, or possibly caused, by faulty nutrition, are other examples of these contacts. Here mention may be made of a case of spondylolisthesis, in a child of well-to-do parents, that lately came to my notice: an example, as it proved to be, of malnutrition in the midst of plenty and of the truth that it is not the food presented to a child but the food eaten and utilized that is of importance. In this case operation by bone-grafting was suggested for the

correction of the deformity: a suggestion fortunately not followed; for the child made a complete recovery, as evidenced by an x-ray examination, after a year's proper feeding combined with properly directed exercises.

It is in such cases as this and in the detection of rachitic and other bony changes which might otherwise escape observation that radiology comes into touch with nutrition. Physical medicine does not, at present, appear to have any direct contacts with nutrition, yet the use of physical methods in endocrine disorders and in certain maladies that may have a malnutrition basis may not be without significance.

OTORHINOLARYNGOLOGY

Nutrition has a close concern for otorhinolaryngology, particularly in view of the changes brought about in mucous membranes by deficiency of vitamin A. These changes, which I shall have the opportunity to demonstrate to you this afternoon, are such as break down the local defences against infection, and may be of localized or widespread distribution. It is common knowledge that malnourished, weakly, and ill-conditioned children are peculiarly susceptible to inflammatory states of the nose, ear and throat. 'It is almost impossible in winter to keep such children in a hospital ward more than a week or two without their developing rhinopharyngitis, otitis, bronchitis or bronchopneumonia' (Holt): a state of affairs recalling the 'hospitalism' of the dark days of surgery prior to the advent of Lister. Such children frequently suffer from adenoids, which may possibly have a malnutritional basis, for I have myself observed the development of adenoid-like outgrowths in the upper respiratory passages of improperly fed rats.

TUBERCULOSIS AND DERMATOLOGY

Concerning tuberculosis and nutrition, one example will suffice: at the Papworth Village Settlement no child born there during the twenty years of its existence has, while a member of the community, contracted tuberculosis of the lungs, bones, joints, cerebral membranes, nor indeed any clinical form of the disease. Yet these children are the offspring of parents who suffer from tuberculosis and are in constant contact with them. How has this remarkable achievement been brought about? (1) By adequate nutrition, which maintains the child's resistance to infection, and (2) by the absence of mass dose infection—procedures which will prevent many other diseases besides tuberculosis. Here it is necessary to emphasize the relation of faulty nutrition to respiratory disease in general. It is a significant fact that one out of every ten sick persons amongst the insured classes in England and Wales suffers from such disease, and that rats fed on a diet in common use by these persons frequently develop such disease. Deficiency of vitamin A is particularly concerned in bringing this about.

In the domain of dermatology the effects of faulty nutrition on the skin are well recognized; semi-starvation, water deficiency, protein deficiency, mineral deficiency (particularly of iron, calcium, phosphorus, and iodine) and vitamin deficiency (particularly of vitamins A, B, and C) all have harmful effects on this organ and its appendages. Amongst them are dry and inelastic skin, roughening, atrophy, laxness, wrinkling, slow growth of hair, staring hair, loss of hair, slow healing of skin wounds, poor and imperfect cicatrices, furunculosis, ulcers, exudative skin diseases such as eczema and seborrhœa, the skin lesions of pellagra, œdema, xerosis, abscesses, inflammatory conditions at mucocutaneous junctions, the papular condition known as 'phrenoderma', hyperkeratosis, petechial hæmorrhages and other scorbutic skin affections.

THERAPEUTICS

It is in the domain of therapeutics that the newer knowledge of nutrition finds scope for practical application. 'Formerly, in planning the patient's food,

physicians thought solely in terms of the local pathological condition, of the harm they might do some impaired organ; now they think chiefly in terms of general physiology, of the good they can do the patient as a whole. It is in most cases the patient who must be treated rather than the disease from which he suffers, and in this treatment nothing is so important as maintaining nutrition. Witness the changes that have come about within recent years in the treatment of such conditions as typhoid fever, gastric ulcer, Bright's disease, hypertension, diabetes, tuberculosis, chronic arthritis, and eclampsia: a change based on the fundamental principles of the correction of food faults and the provision in proper amounts and proportions one to another of the various food-essentials needed for the maintenance of structure and function of organs or parts of the body. In the last resort the patient must, with remarkably few exceptions, heal himself, and it is by adequate nutrition that he can best be put in the way of doing so. Here the newer knowledge comes to the aid of the physician, enabling him, by means of refined preparations, rapidly to satisfy the needs of the body for substances that are in default, and thus to hasten cure.

MEDICAL SOCIOLOGY

The importance of nutrition in medical sociology is evidenced by the programme of work before that section at the present annual meeting, wherein it is given a prominent place; it will, then, speak for itself. But I am constrained in this connection to refer again to the remarkable experiences the late Miss Margaret McMillan mentioned in her book—*The Nursery School* (1930). Here she has described the weakly, ill-nourished, and ill-conditioned children of the slums who come for admission to the nursery school at Deptford: children who are rachitic and bronchitic; children with inflammatory states of the nose, ear and throat; children who have adenoids and dental caries. After they have been nurtured and properly fed for a few years they are, she says, almost all cured of any ailments from which they may have suffered on their entrance to the school. They are all straight and well grown, the average child is well made with a clean skin, is alert, sociable, and eager for life and new

experience..... 'He does not need to see the doctor or the dentist, and he has none of the minor ailments which affect the children of the slums'. Surely, we have in experiences such as this the root of the whole matter. We now know that large numbers of our people have not the means wherewith to provide themselves with proper food even though they had the knowledge to enable them to judge of what is proper; a state of affairs damnatory of our civilization. But it would be wrong to suppose that poverty is the only cause of faulty nutrition. 'Access to abundance of food does not necessarily protect from the effects of food deficiency, since a number of factors—penury, prejudice, ignorance, habit—often prevents the proper use and choice of health-giving foods'. To these impediments to normal nutrition I would add indifference, neglect, and the weak indulgence of their children by many well-to-do parents who foster tastes and habits detrimental to normal growth, nutrition, and health. Education of the people, the better education of ourselves: these are urgent necessities. It may be that the medical curriculum is already overgrown. If so, let it be pruned, let us teach the student less about 'disease' and drugs and more about 'health', more about nutrition, which is the very basis of health.

MEDICAL HISTORY

I come now to the last of the sections—that of the history of medicine. In this history no chapter is more romantic, more inspiring, more replete with hope for the future of our calling and for the well-being of mankind than that dealing with the newer knowledge of nutrition. Its opening pages tell of the dawning idea of the relation of certain diseases, notably scurvy and beri-beri, to defects in food. These are succeeded by others describing the discovery of vitamins. As the story unfolds the numbers of these and of other elements and complexes, found to be necessary for normal nutrition, increase, and the conception of disease as a manifestation of disturbed structure or functions of the body consequent on faulty feeding and on the faulty nutrition resulting therefrom comes into being. Patient research, the discovery of facts, generalizations from facts, the prediction of fresh facts—its pages tell of these. These are the ways of science; these the ways in which the science of nutrition has been built up.

Reviews

THE QUEEN CHARLOTTE'S TEXTBOOK OF OBSTETRICS.—By Members of the Clinical Staff of the Hospital. Fourth Edition. 1936. J. and A. Churchill Limited, London. Pp. xi plus 674, with 4 colour plates and 291 text-figures. Price, 18s.

A NEW edition of this standard textbook has been published three yearly since it first appeared in 1927. This bears witness to the high standard aimed at and attained by the writers of the book. The 1936 edition contains an important addition in the description of the results of the work on the ætiology of puerperal sepsis by Dr. Colebrook in the research laboratories of the Queen Charlotte's Hospital. The section on the toxæmias also has been brought up to date.

This book represents the teaching at Queen Charlotte's Hospital and is written by members of the clinical staff of the hospital. It differs little in the main from the teaching of obstetrics as practised in other London hospitals and it provides an excellent students' textbook of midwifery. It is clearly written and the

illustrations are good. The chapters on antenatal care and the normal and sick new-born babies are fuller than in many textbooks of midwifery. There is a valuable chapter on abdominal pain in pregnancy. The book is essentially practical and it is doubtful if a better introduction to the practice of midwifery could be found. The whole problem of mother and child, attendant and environment is kept in view throughout the book. It can be most thoroughly recommended.

M. N.

A TEXTBOOK OF OBSTETRICS.—By Edward A. Schumann, A.B., M.D., F.A.C.S. 1936. W. B. Saunders Company, Philadelphia and London. Pp. 780, with 581 illustrations on 497 figures. Price, 27s. 6d.

THIS American textbook strikes a British reader 'favorably' by reason of the illustrations which are many and good and have the value of appearing new

and better than the diagrams which one is accustomed to expect in textbooks of midwifery.

The book as a whole falls between the students' textbook and the more advanced works on obstetrics. A large section is devoted to development of the fetus and to obstetrical pathology. The management of pregnancy is given only a very short chapter and the new-born child is dismissed in two pages. One misses reference to the later work on the ætiology of puerperal sepsis but the subject of the toxæmias is discussed at great length.

There is a vast amount of information in this book, but it seems to be presented in a somewhat indiscriminate manner, likely to lead astray any but those with a sound knowledge of midwifery. The opinions expressed are those of an individual and some of them are certainly controversial. The description of the treatment of post-partum hæmorrhage in which the writer so confidently emphasizes the use of packing of the uterine cavity should be read only by the experienced. The teaching on the question of tuberculosis and pregnancy may be true of a country where institutional treatment of tuberculosis is easily obtainable, one doubts whether it could be more widely applied. It is surprising to read that puberty in India is reached at the age of eleven years and in Great Britain at fifteen years. The operation of forceps delivery should, in the opinion of the author, take an hour.

This book is stimulating reading because one so frequently encounters an opinion which seems open to question, but it can only be recommended to those in a position to apply the critical faculty.

M. N.

A TREATISE ON MATERIA MEDICA AND THERAPEUTICS INCLUDING PHARMACY, DISPENSING, PHARMACOLOGY AND ADMINISTRATION OF DRUGS.—By the late R. Ghosh. Fourteenth Edition by B. N. Ghosh, F.R.F.P. & S. (Glas.), 1936. Published by Hilton and Company, Calcutta. Pp. xv plus 724, with 13 illustrations. Price, Rs. 7-8 or 12s. 6d.

THE first edition of the 'Treatise on Materia Medica and Therapeutics' appeared in 1901, nearly 35 years ago. Since then the book has passed through fourteen editions and several reprints. This fact alone bears testimony to the wide range of usefulness and popularity of the book. It is gratifying to note that the present edition (fourteenth edition) under the able editorship of Professor B. N. Ghosh maintains the tradition and the high standard of excellence already set by its predecessors.

Though the original title of the book is retained and the binding and format are generally similar to the previous editions, the present edition is a completely new book from several points of view. The subject-matter has undergone considerable changes with the rapid growth of knowledge of pharmacology and therapeutics. Rational therapeutics is gradually replacing the empirical use of drugs and this tendency is reflected in the section on materia medica where the 'official' preparations are described in more detail and only the more important and commonly used non-official remedies mentioned. Part III deals with the pharmacology and therapeutics of drugs and, in this section, attempt has been made to incorporate the more recent developments in the subject. A few explanatory tracings are included in connection with some of the more important therapeutic agents, but the students would be happier to see more of these tracings. Modern teachers on pharmacology are tending to lay more stress on the subject of chemical constitution and pharmacological action of drugs. Recent advances in organic and synthetic chemistry have clarified many obscure points in this regard and it appears that, if this aspect were attended to more carefully, the teaching of pharmacology would be made simpler and more attractive. It is hoped that, in a future edition, the

author will consider giving added emphasis to this side of the question.

Of the many other useful features of the book, mention may be made of the chapter on serum and vaccine therapeutics and the section on Indian indigenous drugs.

We have nothing but praise for this edition and we hope that it will find a place in the library of every practitioner and medical student.

R. N. C.

AN INTRODUCTION TO DERMATOLOGY: WITH A CHAPTER ON THE THEORY AND TECHNIQUE OF X-RAY AND RADIUM THERAPY.—By E. H. Molesworth, M.D., Ch.M. (Sydney). 1937. J. and A. Churchill Limited, London. Pp. xviii plus 520 containing 151 illustrations in the text and references to the coloured plates of Jacobl's Dermochromes and Semon's Atlas of the Commoner Skin Diseases. Price, 25s.

IN the past few years there has been a considerable number of short books on dermatology and when the reviewer received this volume he wondered, before he opened it, if it would prove worth the effort of its production.

On going through it he was pleasantly surprised, for it is an essentially practical production that cannot fail to be of use to the beginner and general practitioner who only has occasional cases of skin disease to treat. The principal manner in which this book differs from similar short books on dermatology is that the author, instead of being content with saying, as most writers do, that so and so 'may be tried', 'has been found of use by some workers', etc., etc., gives the reader the benefit of his own vast experience and if he has found a certain line of treatment no use he does not hesitate to say so. This dogmatism will perhaps lead to criticism as one naturally does not find one's own experience to coincide completely with that of the author of the book. Nevertheless dogmatic treatment of a subject is an advantage in instructing a beginner who is thereby given a point of view from which he can commence to amass his own experience which may perhaps modify his early learning. On this ground this addition to the dermatological books of the British Empire is strongly recommended.

P. A. M.

PAGET'S DISEASE OF THE NIPPLE AND ITS RELATION TO SURFACE CANCERS AND PRE-CANCEROUS STATES IN GENERAL.—By Dr. Keith Inglis, M.D., Ch.M. (Sydney). 1936. Oxford University Press, London. Pp. 233 with 237 figures. Price, 30s.

THIS is a special work on the particular disease commonly known as Paget's disease of the nipple. As the author has observed in the preface, the book is the result of investigation regarding the morbid histology of Paget's disease. It is very pleasant indeed to observe that the investigation has been carried out in an excellent way and the distinguishing points regarding the nature of Paget's disease have been very clearly elucidated by splendid histological work. As the title of the book denotes, the subject has been studied very thoroughly and allied conditions which clinically appear to be Paget's disease have been included and differentiated from the conditions by histopathological evidence.

The subject has been presented in a scientific way and at the end of each chapter a summary of the discussions has been given. A distinguishing feature of the book is found in the concluding six pages in which the whole subject has been thoroughly discussed and the views of different authorities cited with reference to their respective literature. Lastly, the author's own views supported by unassailable histological evidence have been enunciated. Such a subject, we have no

hesitation in saying will be an useful addition to surgical pathology.

The whole book is comprehensive and very successful. Its get-up, illustrations (237 in a book of 233 pages) and above all the contents are uniformly satisfactory.

We have nothing but wholehearted praise of Professor Inglis's splendid investigations and his achievements. The only point to which we would like to draw his attention is that he has used the term 'cancer' throughout the text.

M. N. D.

RURAL WELFARE IN INDIA IN 1936.—By C. F. Strickland, C.I.E. Humphrey Milford, Oxford University Press. Pp. 54. Obtainable from Oxford University Press, Bombay, India. Price, As. 8.

MR. C. F. STRICKLAND has brought together in a convenient form the activities of the various organizations in India, governmental and other, which are actively helping the rural uplift movement in the country. The Government of India has made a sum of Rs. 3½ crores available to the provincial governments as grants to assist them in developing rural-welfare work. Some provinces such as Madras, Bengal, Bihar, Orissa and Assam are devoting the bulk of their grants to the improvement of water-supply, sanitation and rural roads. Bombay, the Central Provinces, the Punjab and the United Provinces have already had in progress various schemes for the amelioration of the condition of the agricultural population in the villages. The grants made by the Central Government have therefore helped to stimulate further the activities of these provinces.

Mr. Strickland has rightly drawn attention to four points which are essential if the rural welfare movement is to achieve success. The work of the various departments undertaking a share of the work should be co-ordinated and the necessity for linking together the official and non-official agencies should not be lost sight of, if overlapping and waste of effort are to be avoided. The employment of trained personnel is another important matter. They need not be experts in their own subjects, because experts can be called in whenever necessary. But the rural-welfare workers, men and women, should be trained to appreciate the villager's point of view and to win his confidence. Otherwise nothing can be achieved. A third criterion of success is that the cost should be kept down to the minimum. The fourth and perhaps the most important is that of permanence. The zealous servant of the government or the missionary may, through personal influence, bring about temporary improvements in village life, but lasting results can be achieved only through a change in the outlook of the people. All over the world the experience of reformers is that nothing lasting can be accomplished in less than a generation. The children have to grow up under the new conditions in order that the changes may be assimilated into the life of the people. It is therefore an essential condition for success that the governments and other agencies intent on developing rural welfare in India should be prepared to persevere with their schemes for a period of thirty years.

The work of the various provincial governments and of some of the Indian States has been briefly described, with helpful criticisms at each stage. Nor has Mr. Strickland lost sight of other agencies working in the same direction, such as the Red Cross Society and the Harijan Sewak Sabha under the guidance of Mr. Gandhi. The excellent work done by the Y. M. C. A. in several centres in the country deserves special mention.

Lastly, the questions of debt relief, consolidation of agricultural holdings, child marriage and broadcasting for the education of the rural population and for increasing their happiness have been briefly discussed.

The Indian Village Welfare Association, under whose auspices this small book was published, has been founded in Great Britain for the purpose of stimulating interest in the life of the rural population of India and two similar booklets have already been published for 1932 and 1934. The activities of the Association, which include periodical lectures by persons familiar with village conditions in this country as well as the organization of a 'school' every year at Easter time for persons proposing to undertake work in rural India, deserve commendation, especially when we remember that 89 per cent of the population live in the villages.

CONTRACEPTION AS A THERAPEUTIC MEASURE.—

By Bessie L. Moses, M.D. 1936. Baillière, Tindall and Cox, London. Pp. xiii plus 106. Price, 4s. 6d.

THIS book is a report on the medical aspects of the work of the Bureau for Contraceptive Advice which was opened in Baltimore in connection with the John Hopkins University in 1927.

The primary purpose of this bureau was to collect about 1,000 cases of women who required contraceptive advice on therapeutic grounds, to keep careful records for analysis and to obtain data as to the effectiveness of the methods of birth control advised. The patients were referred to the clinic by their own doctors on definite medical indications, and no propaganda was carried out. During the five years in which the bureau operated the data were collected and advice given by Dr. Moses herself with some assistance during the last two years from another woman physician. Careful follow-up work was done at the time of return visits to the clinic, and by letters and home visits if necessary.

One thousand one hundred and fifty-two patients were referred to the clinic, 944 white and 208 negro. The average age at the first visit to the clinic was 30 years and the average number of previous pregnancies was five.

65 per cent of the cases were sent for definite medical reasons of which more than a third was for systemic diseases—venereal diseases and obstetrical indications (such as previous Cæsarean section) and nervous and mental diseases accounted for the majority of other medical reasons. Amongst the other (not strictly medical reasons) were multiparity, indications in the husband, and eugenic reasons.

The method advised in nearly all cases was a vaginal occlusive diaphragm pessary and a spermicidal jelly. A soap and water douche to be used after removal of the pessary was also advised in most cases. The results of advice given were carefully analyzed according to race, intelligence of the patient, continued use of the method, and the occurrence of pregnancy. Approximately 45 per cent of the total number of treated cases attended the clinic and used the method successfully for periods of six months to six years.

Amongst the treated cases in which pregnancy occurred in only 2.7 per cent could this be shown to be due to failure of the method. In the group that became pregnant 71 per cent were of low intelligence. It is stated by the author that no sterility could be shown to have resulted from the use of the methods advised by the bureau.

This report is a valuable contribution to the literature on contraception.

M. N.

PRINCIPLES OF BIOCHEMISTRY.—By Albert P. Mathews, Ph.D. 1936. Baillière, Tindall and Cox, London. Pp. x plus 512. Price, 20s.

THIS is a textbook meant for medical students who have not the time to consult for themselves much of the original literature. As an experienced teacher of biochemistry for nearly 40 years, the author has tried to correlate and synthesize the numerous facts of

biochemistry and to make them a part of a great science which reveals the co-ordinated chemistry of the human body. The whole subject has been discussed under six main sections: (1) The chemistry and metabolism of the glucides, (2) The chemistry and metabolism of the lipides, (3) The chemistry and metabolism of the proteins, (4) The special chemistry of important tissues, blood and connective tissues, (5) The catalytic agents of growth and development, vitamins and hormones, and (6) The income of energy. The chemistry of the compounds dealt with in each section or sub-section has been discussed clearly and briefly, and the latest views about their constitution have been put forward. This is followed by a discussion of the metabolism of these compounds. All practical exercises have been omitted and references to the literature have been avoided since the author did not intend it to be a reference handbook. The subjects have been presented in a logical sequence which makes the book a very pleasant study instead of appearing as an assembly of facts. The lucid manner in which the subjects have been discussed will profit not only the medical student, for whom it has been primarily written, but also any other reader who is interested in this growing and extremely fascinating science of biochemistry.

S. G.

STEDMAN'S MEDICAL DICTIONARY.—By Thomas L. Stedman, A.M., M.D. Thirteenth Revised Edition. 1936. Baillière, Tindall and Cox, London. Pp. xii plus 1291. Illustrated, and with 22 plates. Price, 35s.

It is just three years ago since we had the pleasure of reviewing the twelfth edition of this, one of the best of the medical dictionaries.

One of the reasons for the appearance of the thirteenth edition is that many changes have been made in the names used in the new editions of the U. S. Pharmacopœia and the National Formulary. Considerable additions have also been made as the present edition contains 35 pages more than the previous one.

There is little need to review a dictionary in detail and it should suffice to say that the contents of this book maintain the high standard of usefulness of former editions.

P. A. M.

PRINCIPLES AND FOIBLES OF CANCER RESEARCH—IN REGARD TO ÆTIOLOGY AND NATURE.—By Wm. Reinhoff, Sr., M.D., F.A.C.S. 1936. Waverly Press, Inc., Baltimore, Maryland. Pp. vii plus 200

THIS book is a distinctly remarkable achievement for it is a review of the present position regarding cancer research and a summary of practically all the work done on this subject. To the reviewer whose work lies in other directions and so does not allow leisure to follow cancer research in all its details the book was a revelation and the main impression he received while reading it was that cancer research is somewhat like the disease itself in that it has become thoroughly unwieldy and has invaded all branches of medical science, often, as the author of this small volume shows, without any sound reasoning to warrant it.

The first part or preamble is devoted to considerations underlying research in its widest sense including philosophical and metaphysical discussions and might be read with advantage by any medical research worker, at the outset of his career, whatever branch of research he is going to pursue. The second part is more specially devoted to considerations of cancer research, what lines are considered by the author to be worthy

of pursuit and indicating where cancer research has wandered from the true path into by-ways that have led or will inevitably lead to dead ends.

It is a book that will excite considerable controversy as all the tenets of the author will not be accepted by every experienced cancer research worker, but it is a useful book as it is an attempt to stem the flood of inconsequential and unscientific researches which at present appear to be cumbering the path of real advance, and if it succeeds in this, even only in part, it will not have been written in vain.

Unfortunately the author has not the power of clear expression so it is often difficult to follow him in his somewhat abstruse reasoning, and this difficulty is not lessened by his habit of giving his references in brackets often right in the middle of a long and obscure sentence.

RECENT ADVANCES IN ALLERGY. (ASTHMA, HAY-FEVER, ECZEMA, MIGRAINE, ETC.).—By George W. Bray, M.B., Ch.M. (Sydney), M.R.C.P. (Lond.). Third Edition. 1937. J. and A. Churchill, Limited, London. Pp. xv plus 517, with 107 illustrations including 4 coloured plates. Price, 15s.

THE subject of allergy has made rapid strides since it first became a matter for intensive laboratory investigation about the year 1920, but its progress does not seem to be slowing down. During the last three years—since the last edition of this very valuable contribution to the subject appeared—no very dramatic advances have been made. Nevertheless, much ground has been covered and a new edition incorporating recent work is very welcome.

We naturally turn to asthma as being the type disease of the group. Here the author is probably at his best, as it is a subject to which he himself has given his whole time for a number of years. His account of the treatment of the disease is as simplified as it is possible to make this very difficult and many-faceted subject. Numerous forms of treatment are mentioned but they are arranged methodically under suitable headings, even if he does fall back on a non-committal expression, such as, 'success has been claimed', rather often. He lays great emphasis on breathing exercises and gives detailed instructions how these may be carried out.

Other sections are equally satisfactory. The book is well referenced and there is an author's as well as a subject-index, and in every way the book is a worthy member of this most excellent series.

L. E. N.

APPLIED PHYSIOLOGY.—By S. Wright, M.D., F.R.C.P. Sixth Edition. 1936. Oxford University Press, London. Humphrey Milford. Pp. xxii plus 686. Illustrated. Price, 20s. Obtainable from Oxford University Press, Bombay, India.

To the physician, the publication in 1926 of Sampson Wright's *Applied Physiology* was an event of very great importance, as it gave him an opportunity of revising and bringing up to date his knowledge in the subjects in physiology that were directly applicable to his every-day practice, without re-reading his textbooks and wading through the physiological journals. To the post-graduate student studying for higher examinations, it was even more important.

The book was a new departure and one that had a marked effect on medical practice amongst English-speaking people. That was just ten years ago. In the intervening years there have been four new editions and many reprintings of this excellent book, so, it is to be hoped, the author and the publishers have reaped their reward.

There is little that need be said about the present edition except that it has been brought completely up to date. There has been a revision of every section and in some considerable re-arrangement.

In the chapter on the blood a new coloured plate has been added, and so much recent work has been included in this chapter that, without referring back to a previous edition, one can say that it has been entirely re-written. The author, we are glad to note, emphasizes the meaninglessness of the expression 'percentage of

hæmoglobin', so frequently used without any mention of the standard, in medical literature.

The book still remains the most valuable non-clinical book that the practitioner can possess.

Abstracts from Reports

ANNUAL REPORT ON THE WORKING OF THE CIVIL HOSPITALS AND DISPENSARIES IN THE MADRAS PRESIDENCY FOR THE YEAR 1935

Labour cases.—During the year 90,910 normal and 15,913 abnormal labour cases were conducted in all classes of medical institutions, the corresponding figures for 1934 being 84,599 normal and 13,941 abnormal. The increase in the number of labour cases shows the tendency on the part of the female population to come to medical institutions for maternity relief.

Kala-azar.—During the year under report 2,130 cases of kala-azar were treated in all the medical institutions in the Presidency, of which 857, 566 and 490 were treated in the districts of Madras, Ramnad and Tinnevely respectively.

Tuberculosis.—The total number of patients treated for tuberculosis (tuberculosis of the lung and other tuberculous diseases) in all the medical institutions during the year was 77,412 with 1,413 deaths. The superintendent, tuberculosis hospital, Madras, reports that on an average the period of stay of the cases that improved by treatment was 61 days. Observation of the employees of the government press, Madras, was continued during the year by the director, tuberculosis institute, Madras. The director reports that an attempt has been made for the tuberculosis institute to serve as a centre for after-treatment of cases discharged from other hospitals and sanatoria in the presidency and outside.

Anti-rabic treatment.—During the year 192,269 doses of anti-rabic vaccine have been issued to all the authorized treatment centres in Southern India. The total number of patients who received treatment during the year was 535 at the Pasteur Institute, Coonoor, and 14,084 at all local centres. Thirty-one new centres were opened in the presidency. Twenty-one medical officers were trained at the Pasteur Institute, Coonoor, in the technique of anti-rabic treatment during the year, for the charge of the newly opened centres.

Leprosy.—Steady progress was maintained in the leprosy campaign during the year 1935. Local boards and the public are showing increased interest in the work. The number of clinics at the end of the year was 441, of which 36 were opened during the year. All the government medical institutions and almost all local fund and municipal medical institutions and about 50 subsidized rural dispensaries have leprosy clinics. More clinics can be opened in the subsidized rural dispensaries if facilities are given. Medical officers are becoming less pessimistic about the work and many of them are working whole-heartedly. In some places efforts have been made by feeding them to persuade the poorer patients to be more regular in getting themselves treated. About 40,000 patients were treated during the year and about 809,000 injections were given to them at the clinics. The results in those who persevere in treatment were satisfactory, the chief aim being to arrest the disease. The same 12 leper asylums were functioning with a daily average strength of about 2,100 and with several patients on their waiting lists. They are now adopting the policy of housing the treatable infectious cases only with a view to benefiting them and the community at large by 'hospitalizing' them.

The district leprosy councils have been taking some interest in seeing that the work in the districts does not suffer for want of finance by addressing local boards and by stimulating public opinion. The chief leprosy officer in addition to his duties as a group leprosy officer has been co-ordinating the work done in all the clinics and asylums, directing the work of the group leprosy officers and supervising the work in the presidency. As people come to know more and more about the disease better co-operation may be expected.

Venereal disease.—The working of the venereal departments continues to be satisfactory, both in quantity and quality. Five thousand seven hundred and fifty new cases (males) and 1,400 new cases (females and children) were examined and treated in the venereal department of the Government General Hospital, Madras. The average daily attendance in that department consisted of 153 cases, of which 21 were new cases. Nine male doctors were trained in the department during the year. Propaganda by way of distribution of leaflets to the patients attending the department also forms part of the daily routine.

Honorary medical officers.—The Government passed orders on the recommendations of the committee appointed to extend further the system of honorary medical officers and the rules were revised with reference to the committee's recommendations. Applications were invited for appointments of honorary medical officers and they were appointed in many of the medical institutions in this presidency.

Medical education.—During the year under report medical education in this presidency has maintained its reputation and several important investigations and researches were conducted by the staff of the two medical colleges. The year 1935 has been the centenary celebration of the Madras Medical College when His Excellency Lord Erskine, the then Governor of Madras, spoke very highly of the medical education in general and the Madras Medical College in particular. To get the required number of pupils to join the Lady Willingdon Medical School for Women, the Government increased the number of stipends to 15 and also reduced the fees for non-Madrassi students.

THE MISSION TO LEPERS, SEPTEMBER 1935 TO AUGUST 1936

A REVIEW OF THE YEAR'S MEDICAL RETURNS

By JOHN LOWE

(Research Worker in Leprosy, School of Tropical Medicine, Calcutta)

Honorary Medical Adviser, Indian Auxiliary

I HAVE read with interest the medical returns for the year 1935 of the work done by the Mission to Lepers in 43 different stations in India. The figures are impressive—roughly 17,000 patients treated, nearly 9,500 as inpatients and the rest as outpatients, nearly 7,000 patients showing improvement, 1,463 showing arrest of the disease and 771 inpatients discharged, most of them without deformities.

From my personal knowledge of the work of some of these institutions, I can realize what skill, patience and hard work have been necessary to produce these

results. I know the factors which militate against the production of better numerical returns, the severe cases remaining in institutions many years, and the consequent difficulty of finding room for the admission of many slighter cases which might later help to swell the number reported as arrested or discharged. Nevertheless each year the number of patients treated, and the number of patients showing improvement and arrest of the disease steadily but slowly increase. It is clear that the Mission is giving every possible encouragement to the development of the medical side of the work and that the medical staff and resources of the Mission are being used to very great advantage.

The institutions of the Mission, by isolating and treating so many patients, are doing work of great value from the medical and public health standpoint. Their steady work, year after year, is a very valuable contribution to anti-leprosy work. Other types of work are needed, work on a bigger scale, general propaganda and survey work, outpatient treatment centres, home or village isolation and so on, and to this work the Mission sometimes lends a helping hand, but the adequate maintenance of its own institutions is the most valuable contribution which the Mission can make.

The figures given in the medical report corroborate one's general impression that, when the disease is well established in the body, to get clinical improvement is fairly easy in many cases, but to get arrest of the disease is difficult and sometimes impossible. The limitations of treatment of leprosy are apparent. How can the Mission use its resources and develop its work to the best advantage?

There is an obvious need for increased effort to control the disease in childhood before it has obtained such a hold that arrest is difficult or impossible. Most of the Mission's institutions have homes for healthy children of leper parents and for leper children. Such homes should provide the best hygienic conditions possible and adequate medical supervision in order to give the children the best chance of overcoming slight or latent infections. The extension of this type of work is greatly needed and it is a type of work which can in most places be best undertaken by the Mission. It must, however, not be overdone. It is, I think, wrong to admit children to leprosy institutions and homes unless there is a real necessity for doing so, unless they either have the disease in an active form or else are living in close contact with infectious people and running a grave risk of contracting the disease. There are in India many thousands of such children. Temporary admission of healthy children exposed to infection until it is clear that they are not suffering from the disease, that their physical condition is really good and that some other suitable arrangements can be made for them, and more permanent admission of those who are showing definite signs of active leprosy, might save many of these children. The Mission might very well, during the next few years, concentrate on the further development of this side of their work along sound lines.

STATISTICS OF TREATMENT, 1935

Inpatients

Inmates under treatment at end of year ..	6,597
Inmates who received treatment for three months and upwards ..	9,420
Much improved ..	3,101
Slightly improved ..	2,373
Became worse ..	464
Had to stop treatment ..	209
Apparently stationary ..	766
Died or left ..	1,070
Cases arrested <i>without deformity</i> ..	920
Cases discharged <i>without deformity</i> ..	684
Cases arrested <i>with deformity</i> ..	401
Cases discharged <i>with deformity</i> ..	87
Cases arrested in a previous year but relapsed during the year ..	102

Outpatients

Number of outpatients treated ..	6,679
Cases improved ..	1,139
Cases arrested or became symptom-free ..	142

SIXTH ANNUAL REPORT OF THE ASSOCIATION FOR THE PREVENTION OF BLINDNESS, BENGAL, 1935-36

1. INTRODUCTORY

IN presenting the sixth annual report of the Association for the Prevention of Blindness, Bengal, the committee are glad to report that the activities of the association continue to grow steadily. Unfortunately, progress must of necessity be slow owing to still limited finances. Much however has been accomplished in the year under review, and it is gratifying to know that the popularity of the campaign in the prevention of blindness is more apparent amongst the lay public in Bengal. The committee are very pleased to announce that one of their principal aims has now been achieved, namely, the first travelling eye dispensary which is the first of its kind to be started in India. It owes its existence largely to a gift of Rs. 35,000 which has been presented by the Committee of Their Majesties' Silver Jubilee Fund. This sum represents the budget for maintaining the dispensary for a period of five years. The initial cost of the motor ambulance and its equipment and appliances have been met from the general funds of the association.

The Jubilee Travelling Eye Dispensary started its work on the 28th March, 1936. It has been sent to the Burdwan division and will penetrate into the remotest villages and carry with it the benefits of modern ophthalmology and preach the gospel of prevention. Particulars of the work carried out by this travelling dispensary will be given in next year's annual report.

To medical men who have worked in India it has long been recognized that the great prevalence of blindness in India is due to the backwardness, ignorance, poverty and apathy of large masses of the people. In the villages and even in the towns also there is submerged a great mass of blind people who think themselves and are thought by their relations and friends to be irretrievably blind and who by a small operation could have their vision restored or at least be given a considerable degree of sight. Very commonly these are cases of cataract; cataract comes on early in India, and is often seen in people as young as 30 years of age. The greater proportion of these people could have their sight restored. Some of these go to hospital, especially if they are within fairly easy distance, but very great numbers do not go. They are too ignorant and fatalistic, too timid or perhaps they prefer to wait till the travelling quacks come along to couch their cataracts with disastrous results. Then there are juvenile cataracts which occur in children and the congenital ones which can all be cured by a simple operation performed by an eye doctor. One sees numbers of corneal opacities, a man, woman or child suffers from some kind of opthalmia which, if it does not destroy his eyes altogether, leaves behind dense opacities and when these cover the pupils and result in blindness. But if, as there often is in such cases, any clear portion of the cornea is left intact, then there is always the chance that by the operation of iridectomy or the cutting of a new pupil in the clear portion of the cornea the sufferer may be restored to a measure of vision. But most of the people in the remote parts of the country do not know this and so they remain blind.

Epidemic dropsy, more commonly but erroneously called by the lay public beri-beri, is extremely common throughout Bengal. It affects all ages; even children do not escape the disease. Glaucoma affecting both eyes is a very common complication and unless treated

by an eye doctor immediately leads to partial or complete blindness from optic atrophy. Large numbers of people become blind from this terrible disease and yet if they would only undergo a small operation in time their eyesight would not have been lost.

One sees large numbers of cases of entropion, where owing to the effects, generally of trachoma or granular ophthalmia, the eyelashes of the patient are turned into the eye and the cornea is slowly sloughed away. These cases call for operation and can be alleviated in that way and the sight saved.

Then again there are vast numbers of people suffering from inflammatory eye diseases which, if left untreated, will lead to loss or impairment of vision and which from their infectious nature are a source of danger to their relations and friends. Now all these cases of cataract, glaucoma, opacities, inflammatory diseases want ferreting out and helping, and it can be quickly realized to what an enormous benefit a travelling eye dispensary can be in carrying out this work.

Prevention is still more important than the actual curing of eye diseases. For, in addition to the multitude of partly or totally blind people who can have their sight restored by operation or treatment, there is still a very large population who cannot be cured but if they had been seen at an earlier stage their sight would never have been lost and their blindness could have been prevented. It is unfortunately not realized by the public that every day, year after year, the same process is going on, the process of recruiting the ranks of the blind out of the numbers of people suffering from eye diseases which, if not treated, will result in total blindness. There are, according to the census returns, some 600,000 blind in India and it is probable 400,000 to 500,000 need not have been blind if they were properly treated in time, and as the older people die off their places are taken by others and in every generation four or five hundred thousand people go blind who should never have been so.

Ophthalmia neonatorum can be easily prevented by prophylactic treatment which consists in putting 1 per cent silver nitrate into the baby's eyes immediately after birth.

Smallpox is still very common in Bengal and a frequent cause of blindness; smallpox would be non-existent if vaccination and re-vaccination every five years were carried out in all persons.

In matters of prevention as well as in treatment it can be seen of what tremendous use a travelling eye dispensary can be in the villages of Bengal.

Until such time as there are sufficient well-equipped eye hospitals scattered throughout Bengal, and this will take very many years, it is the ambition of the Association for the Prevention of Blindness, Bengal, to have as a minimum five travelling eye dispensaries, namely, one for each division.

2. PROPAGANDA WORK

During the year more coloured posters were prepared and printed and distributed through the Bengal Branch of the Indian Red Cross Society to various hospitals and dispensaries in the province. They were also distributed to medical men and others interested in the movement of prevention of blindness. There was a great demand for these posters and they received great praise from all quarters. It has been found by experience that posters which are simple and colourful attract the interest of the public and are one of the most useful ways of instruction in methods of prevention of blindness.

Magic lantern slides form another important part in propaganda work. The association is well equipped with coloured and simple slides which are excellent. It possesses two magic lantern slide lectures entitled:—

- (1) 'Care of the Eyes' with 32 slides.
- (2) 'Prevention of Blindness' with 54 slides.

These slides have been made by the Y. M. C. A. Lecture Department, 5, Russell Street, Calcutta, from

posters belonging to the association. Copies of these slides can be obtained at a small cost at the above address and copies of the lecture can also be obtained from the office of the Association for the Prevention of Blindness, Bengal, at the Eye Infirmary, Medical College Hospitals, Calcutta.

As mentioned in last year's annual report, the sum of Rs. 1,650 was presented by the Indian Red Cross Society for lectures and educating teachers in the schools and colleges of Bengal, in prevention of blindness. These lectures still continue to be given and are very popular. They are given by trained ophthalmologists under the direction and supervision of the honorary secretary of the association. They are essentially practical and consist of simple methods in prevention and treatment together with magic lantern slide demonstrations. A special syllabus has been prepared and printed for the guidance of these lecturers. They are paid Rs. 10 per lecture, e.g., Rs. 20 for two lectures which constitute a course for each school or college. Difficulty is being experienced in finding the travelling expenses of the lecturers, otherwise lectures and demonstrations could be given in more districts and subdivisions in Bengal. Judging by the letters of appreciation which are being received, these courses of lectures are very popular and supply a much needed want. The lectures are primarily intended for teachers but senior students are also encouraged to attend and they do so in large numbers. A discussion is invited after each lecture and questions explained and answered by the lecturer.

The association is well equipped with booklets on subjects which are important in the prevention of blindness and the care of eye diseases. They are written by ophthalmologists in very simple language and well illustrated. These booklets are being gradually translated into Bengali and Urdu. Requests for copies of the booklets and posters keep coming from different parts in and outside Bengal.

A new cinema film in two reels entitled 'Lamps of Life' has now been completed and is most excellent. This film has been made partly from actual scenes in the Eye Infirmary, Medical College, Calcutta, and partly in the mofussil of the Burdwan district. The association is much indebted to Mr. R. Johnston, I.C.S., District Magistrate of Burdwan, who has taken the photographs and has taken tremendous trouble to make the film a success. The characters are Bengalees and the captions are written in English and Bengali. Copies of this cinema can be obtained from Messrs. Houghton Butcher (Eastern), Ltd., 10, Hungerford Street, Calcutta, at a cost of about Rs. 100.

It is hoped in the coming year to show this cinema freely in Calcutta and copies will be provided for the Jubilee Travelling Eye Dispensary and lecturers in the mofussil. Cinema films are undoubtedly far and away the best method of spreading information on prevention and treatment of blindness.

During the year, epidemic dropsy again broke out in many parts of Bengal. Outbreaks also occurred in parts of Bihar, the United Provinces and Burma. The disease is almost exclusively confined to Bengalees. It is more commonly called beri-beri by the public although it is an entirely different disease. As pointed out in last year's report, glaucoma is a frequent complication of epidemic dropsy and, unless the correct treatment is given, it leads to partial and often complete blindness. It is a disease that can, to a large extent, be prevented and information for its prevention and cure has been disseminated on many occasions through the lay papers and the radio with satisfactory results. Large numbers of patients suffering from epidemic dropsy glaucoma, in all its stages, present themselves at the various hospitals in Calcutta for treatment.

If one visits the various outpatients' departments at the eye hospitals in Calcutta, one sees piteous sights of young, adults, middle-aged and old people blinded by this disease. A booklet on epidemic dropsy glaucoma has been brought out by the association and copies of this can be obtained on request.

As in the past the association took a prominent part at the Annual Health Exhibition held in the Museum, Calcutta, and ran the Blindness Stall. Many other health exhibitions held in and out of Calcutta were helped by the association with materials for sections on prevention of blindness.

[The above abstract shows what a live and progressive body this association is, and that in the six years of its existence it has maintained its progress in spite of the fact that this period included the worst years of trade depression when even firmly established charitable organizations suffered severely. The executive of this association is to be congratulated on the manner in which it is steadily expanding its activities and we know of no more worthy object to which the charitably-minded might subscribe, for it is clear from this report that any funds available are carefully and economically spent so that the subscriber can feel assured his money is being expended in full for the object for which it was given.]

ANNUAL REPORT ON THE CIVIL HOSPITALS AND DISPENSARIES IN THE CENTRAL PROVINCES AND BERAR FOR THE YEAR 1935. BY COLONEL N. M. WILSON, O.B.E., I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, CENTRAL PROVINCES

Dispensaries.—The number of hospitals and dispensaries at the close of the preceding year was 336. During the year 1935 four new dispensaries were opened, viz, the private non-aided mission dispensary at Patpara in the Mandla district, the cheap plan dispensary at Fatekherda in the Buldana district, Shrimati Laxmibai Deshmukh Women's Hospital at Murtizapur in the Akola district and the Ramrama Mine Dispensary in the Balaghat district. Owing to the closure of the Pulgaon Mill, the dispensary attached to that mill was closed during the year. Thus, the number of hospitals and dispensaries open at the close of the year was 339, of which 164 were rural and 175 urban.

Taking into account the number of dispensaries at which the public ask for free attendance, the average area covered by a dispensary comes to 476 sq. miles, while the average population works out to 73,846. This is a proof that medical relief in the province is inadequate and the opening of more dispensaries is a necessity for the spread of medical relief in rural areas. But in these days of economic depression deputy commissioners find it very difficult to raise money by private subscriptions to fulfil the conditions for opening cheap plan dispensaries; so unless the economic condition of the villagers shows a decided improvement or the condition of raising a local contribution of Rs. 8,500 on account of endowment fund and half building charges is relaxed, further progress in the matter is not possible.

Mayo Hospital.—The general condition of the buildings which comprise the Mayo Hospital is very poor. There is no modern system of sanitation throughout the building and its area; in consequence, patients are put to great discomfort and inconvenience. There is an inadequate water-supply which is dependent on the local town supply; no system exists of overhead tanks by which the hospital can be regularly supplied with water for drinking and ablution purposes.

The nurses' quarters, even from a low standard, leave much to be desired and in consequence the civil surgeon finds great difficulty in retaining the services of capable and well-trained nurses. The ward equipment which includes blankets and sheets is poor and totally inadequate. In general, the Mayo Hospital, though considered the chief hospital of the province, is far below the standard recognized for a modern hospital.

Distribution of medical personnel.—The strength of the medical personnel working in all classes of hospitals and dispensaries in the province during the year under report was 1,146 (1,089), of which 123 (118) were in the

hospitals and dispensaries at provincial headquarters, 692 (648) in those at district headquarters and other urban areas and 331 (323) in those in rural areas.

Nurses.—The staff of nurses at the provincialized hospitals is still inadequate and, as stated last year, unless money is available for providing proper quarters for nurses, no increase in the nursing staff is possible. The three training centres for probationer nurses—the Mayo Hospital, Nagpur, the Victoria Hospital, Jubbulpore, and the Irwin Hospital, Amraoti—continued during the year, while the one at Raipur could not be opened for want of nurses' quarters. Staff nurses were employed at the main hospitals at Saugor, Wardha and Akola.

Honorary physicians and surgeons.—Independent medical practitioners held honorary appointments of physicians, surgeons, dentists and specialists in eye, ear, nose and throat departments at the Mayo Hospital, Nagpur, the Victoria Hospital, Jubbulpore, the Irwin Hospital, Amraoti, the Silver Jubilee Hospital, Raipur, and the Main Hospital, Akola.

Malaria was more prevalent during the year and showed an increase of 80,024 over the figures of the preceding year. The increase was noticed in all districts, excepting Drug.

The number of cases treated for smallpox during the year was 462 (729), of which 84 were vaccinated, 191 not vaccinated, while the vaccinal condition of the remainder was not known.

The local Government has approved of the proposal to establish a tuberculosis clinic at each divisional headquarters of the province and to provide beds at the Union Mission Tuberculosis Sanatorium at Pendra Road in the Bilaspur district.

Financial condition.—The year opened with a cash balance of Rs. 13,40,999, and closed with a balance of Rs. 13,43,010, showing an increase of Rs. 2,011. The total receipts, including the opening balances, amounted to Rs. 26,74,249 (Rs. 25,79,304). The amount of Government contributions paid during the year was Rs. 7,05,737 (Rs. 6,99,898), while the contributions from local and municipal bodies amounted to Rs. 2,92,992 (Rs. 2,49,395). The other receipts items were Rs. 65,717 (67,619) from fees and contributions from patients, Rs. 78,743 (72,185) from funds collected by hospital committees and Rs. 1,90,061 (1,53,963) from miscellaneous sources.

Some of the local bodies have been irregular in the paying of their contributions. The present economic depression is largely responsible for this irregularity; unless payments are regular, it will not be possible to run the dispensaries efficiently. The Deputy Commissioner, Wardha, reports that it may be advisable to deduct the amounts of the contributions from the Government grants for general purposes in the case of those local bodies which have made persistent defaults in the past.

Ticket system.—The half-anna ticket system was continued as an experimental measure during this year also at hospitals and dispensaries situated at *tahsil* and district headquarters. The continuance or otherwise of this system will be considered in due course on receipt of reports, regarding its utility, from local authorities. In any case, the time has come when funds should be raised by special taxation for the upkeep of hospitals. The total expenditure during the year amounted to Rs. 13,31,239 (Rs. 12,40,779), which shows an increase of Rs. 90,460.

Silver Jubilee Fund.—The Silver Jubilee of His Majesty the late King-Emperor marks a memorable period in the history of medical activities in this province. The private generosity displayed on this occasion has resulted in the establishment of two women's hospitals in Berar and the carrying out of improvements to existing medical institutions in the province, many of which, starving for want of funds, have been relieved to an appreciable extent.

The Central Provinces and Berar branch of the Indian Red Cross Society has decided to place at the disposal

of Government a sum not exceeding Rs. 40,000 from its share of the Silver Jubilee Fund partially to meet the cost of the tuberculosis scheme enumerated above. It has also distributed a sum of Rs. 73,695 to various hospitals and dispensaries in the province for the relief of the sick. The Dufferin Fund has decided to distribute from its share of the Silver Jubilee Fund a sum of Rs. 1,66,000 to the different hospitals in the province for the treatment of women and children.

Septic tank latrines.—Literature on septic tank latrines was printed and distributed along with copies of plans to all civil surgeons; in consequence, great strides have been made in the construction of septic tanks for the disposal of sewage at hospitals throughout the province. I hope that this system will be adopted throughout the province and once and for all do away with the appalling corrugated iron latrines which are an eyesore to any institution.

SIXTY-EIGHTH ANNUAL REPORT OF THE DIRECTOR OF PUBLIC HEALTH OF THE UNITED PROVINCES OF AGRA AND OUDH FOR THE YEAR ENDING 31ST DECEMBER, 1935

GENERAL HEALTH OF THE PROVINCE

THE death rate in 1935 in these provinces from all causes showed a decrease of 1.97 as compared with the figures of the preceding year, the rates for the two years being 24.78 and 26.75, respectively, per thousand of population. The decrease was chiefly noticeable under cholera and plague.

In the table appended below have been compared the death rates from the most important diseases and it would appear that 1935 has shown particularly low death rates in a few cases as compared to decennial averages:

The total quantities of potash permanganate, kaolin and essential oils mixture supplied during the year from the provincial allotments were 44,106, 8,987, and 2,154 lb., respectively.

The scheme regarding early reporting of outbreaks of cholera by patwaris in the districts of Gorakhpur, Basti and Azamgarh has been extended to another year.

Inoculations.—The total number of inoculations performed by different agencies including travelling dispensaries was 207,620—115,026 were performed by travelling dispensaries, 48,674 by district health staff and the remaining 43,920 by other agencies.

Plague.—Twenty-three thousand and nineteen deaths were due to plague during the year under review against 47,688 in the previous year. The rates per 1,000 of the population for the two years were, respectively, 0.47 and 0.98 and the mean for the previous five years was 0.50.

The mortality from plague during the year under report has shown considerable decrease since 1925 excepting the years 1927, 1930, 1932 and 1933.

The highest mortality (6,426) occurred in April and the lowest (54) in August.

Inoculations.—The total number of inoculations performed was 207,991 of which 102,411 inoculations were performed by travelling dispensaries (including reserve and temporary medical officers), 77,286 by district health staff and 28,294 by different agencies. Plague inoculations are now becoming popular particularly amongst educated people.

Evacuation.—Evacuation of infected dwellings as usual proved useful in checking the spread of the disease. Rs. 6,632 were placed at the disposal of district magistrates to assist people in evacuating their houses and for other anti-plague measures.

Rat destruction.—Anti-rat campaign was carried out in 22 districts, 36 municipalities and 6 notified areas. Rat destruction was mainly carried out by means of barium carbonate and rat trapping. In addition to this

Chief causes of mortality	Death rate per mille for 1934	Death rate per mille for 1935	Average death rate for preceding ten years 1925 to 1934	Increase or decrease as com- pared with 1934	Increase or decrease as com- pared with decen- nial average
Cholera	0.66	0.21	0.59	— 0.45	— 0.38
Smallpox	0.31	0.54	0.18	+ 0.23	+ 0.36
Plague	0.98	0.47	0.78	— 0.51	— 0.31
Fever	20.04	19.20	18.45	— 0.84	+ 0.75
Dysentery and diarrhoea ..	0.37	0.38	0.30	+ 0.01	+ 0.08
Respiratory diseases ..	0.96	0.95	0.73	— 0.01	+ 0.22
Injuries	0.43	0.41	0.45	— 0.02	— 0.04
All other causes	2.99	2.61	2.78	— 0.38	— 0.17
All causes	26.75	24.78	24.29	— 1.97	+ 0.49

Cholera.—During the year under report cholera accounted for 10,412 deaths against 31,903 in the previous year. The rates per 1,000 of the population for the two years were, respectively, 0.21 and 0.66 and the quinquennial average was 0.58. The maximum mortality (1,907) occurred in April and the minimum (8) in December.

Anti-cholera scheme.—For want of funds this scheme could not be extended to any more districts than 23 in which it has been in operation for the last several years.

cyanogas fumigation was also started in the districts of Moradabad, Saharanpur, Muzaffarnagar, Meerut, Bulandshahr and in the municipalities of Meerut, Cawnpore and Hardwar, but had to be stopped for want of funds. The total number of rats killed was 2,167,087. Most of the local bodies appreciated this measure and continued it from their own funds even when the Government grant was not available. It is advantageous to continue anti-rat campaign from year to year as this minimizes chances of outbreaks of plague. Cyanogas fumigation deserves more extensive trial and

efforts will be made to push it on as funds are available.

Four thousand two hundred and twenty pounds of barium carbonate were supplied free of charge to districts and municipalities and a grant-in-aid aggregating Rs. 6,785 was given to district magistrates and local bodies for expenses on preventive measures.

Disinfection of plague-infected houses was done by means of slow fire or Indian torch flame. This has proved to be the cheapest and most effective measure of disinfection.

Smallpox.—Smallpox was responsible for 26,032 deaths in 1935, against 14,817 in the preceding year. The death rates for the two years were 0.54 and 0.31 respectively, and the quinquennial average 0.18. Of the 26,032 deaths, 6,432 occurred amongst children under one year of age, 9,282 between the ages of one to ten years and the rest among adults. The highest mortality (5,264) was recorded in May and the lowest (260) in October.

Fevers.—During 1935, fevers accounted for 929,298 deaths as compared with 970,289 in 1934, yielding a death rate of 19.20 and 20.04 respectively. The quinquennial average was 18.81. The maximum mortality (101,557) was recorded in June and the minimum (64,167) in December. Malaria was responsible for 813,591 deaths, other fevers for 81,907, measles for 23,460, enteric fever for 8,578, cerebro-spinal fever for 756, influenza for 437, relapsing fever for 213, diphtheria for 105, kala-azar for 101, typhus for 76 and acute poliomyelitis for 74.

Tuberculosis.—During 1935, 5,698 deaths from tuberculosis were registered in the municipalities of the United Provinces against 4,402 in the preceding year. Seven thousand three hundred and twenty-five deaths were returned from phthisis during the year, 6,952 in urban areas and 373 in rural areas.

Dysentery and diarrhoea.—The total number of deaths due to dysentery and diarrhoea during 1935 was 18,283 against 18,140 in 1934. The corresponding death rates for the two years were 0.38 and 0.37 respectively, and the quinquennial average 0.31. The highest number of deaths occurred in May and June, the number for each month being 2,184 while the lowest number (854) was recorded in January.

Respiratory diseases.—These diseases were reported to have caused 46,270 deaths during the year under report against 46,567 in the preceding year, the death rates for the two years being 0.95 and 0.96 respectively. The mean for the previous five years was 0.78. The maximum number of deaths (5,194) was returned in May and the minimum (3,006) in July.

Cerebro-spinal meningitis.—Seven hundred and fifty-six deaths were reported from this disease during 1935—474 from towns and 282 from rural areas.

The disease was found usually to set in suddenly with irregular fever, intolerable piercing headache, repeated vomiting with rigidity in neck and dilated pupils in most cases. Positive Kernig's sign and delirium were also noticed in many cases. Moreover such motor defects as defective hearing and dimness of vision, aphasia, hemiplegia and flaccid paralysis with retention of urine were also observed in a certain number of cases. The unusual and grave complication during the convalescent period of the disease noticed was the development of thyroiditis which proved to be fatal in practically all cases in which it occurred.

The disease, though contagious, was found to be irregular in its distribution. The number of proved cases of direct contagion was very small. Unfavourable living and housing conditions, which are frequently a contributory cause of spread of other infectious diseases, appear to have played a much smaller part in the propagation of cerebro-spinal meningitis. Direct contagion therefore cannot be regarded as a very serious factor.

The majority of the cases occurred in persons between 10 to 30 years of age, than 35 to 45 years of age.

Children under two years and persons above 55 years were the least affected. It was observed that people of all communities were susceptible to the disease, but males were comparatively more affected than females. Cases were mostly reported from amongst the poorer classes.

Cases were mostly treated in dispensaries where specific treatment with lumbar puncture and repeated injections of anti-meningococcus serum were given.

Epidemic dropsy (so-called beri-beri).—There were 380 deaths from this disease—339 in urban area and 41 in rural area. The disease, though present in Benares in the month of October 1934, did not attract the attention of the general public till the end of November when cases began to be reported in large numbers. The disease appeared to have been imported into Benares city in the Bengali community from the presidency of Bengal and the neighbouring districts of the Bihar Province. Three hundred and four deaths were returned from Benares city alone.

The onset of the disease was insidious. The disease ran a course of four weeks to a few months. Only in a few cases was the onset sudden and the course less than a week. Generally the disease began with diarrhoea or nausea, which passed off unnoticed. The first warning came on with swelling of the shins which pitted on pressure, shortness of breath, palpitation of heart and low fever. Sometimes there were muscular pains, feeling of weakness or defective vision.

The disease was primarily confined to the Bengali community living in overcrowded, damp and ill-ventilated localities on the river-side wards of the town. It then spread to other communities and a few cases also occurred amongst Mohammedan and non-Bengali communities.

Investigations were made by the local officers to find out the possible causation of the disease. Samples of flour, mustard oil and rice were taken from several big shops and analyzed, but nothing definite could be elicited.

The measures adopted to check the spread of the disease were as follows:—

- (1) The houses where cases occurred were disinfected.
- (2) People were advised to take plenty of raw tomatoes, green vegetables, viz, carrots, peas, turnips, onions, salad and lettuce.
- (3) Leaflets giving symptoms and preventive measures were distributed. Posters were also printed and posted in streets and lanes.
- (4) Lectures were delivered by the hygiene publicity bureau.
- (5) Special attention was paid to the sanitation of the infected localities and sanitary inspectors were directed to keep strict watch on the sale of rotten fish, meat, eggs, fruits and vegetables in markets.
- (6) Samples of rice, atta and mustard oil were taken from the various shops of infected areas and sent to the public analyst for examination and report.
- (7) Vendors were persuaded to expose hand-milled rice for sale.
- (8) Overripe, decayed and rotten fruits and food articles were destroyed whenever detected.

FAIRS AND FESTIVALS

During 1935, the most important fair was the Magh Mela which was held at Allahabad from 14th January, to 18th February, 1935. The gathering on the chief bathing day (*Amavasya*) was ten lakhs. The usual medical and sanitary arrangements, such as inspection of pilgrims travelling by rail and by road, the essential conservancy arrangements in the fair area, etc., were organized and guided by the assistant director of public health. Adequate arrangements for the supply of water were made. The wells in the mela area as well as those in Arai and Jhusi villages were permanganated periodically. Articles of food exposed for sale were regularly inspected. Temporary regulations under the Epidemic Diseases Act were enforced in the mela area

and in the Allahabad municipality. The standard of sanitation throughout the *mela* was kept at a very high standard and there was an entire absence of flies during the whole *mela* period. The general health of the pilgrims was excellent. Out of the seven cases of cholera detected in the *mela* area, five were imported. They were all admitted into the infectious diseases hospital. Vigorous measures were taken to check the spread of the disease. The contacts were given essential oils mixture and were inoculated and 621 anti-cholera inoculations were done. The activities of the hygiene publicity bureau in connection with this fair consisted of a public health exhibition, cinema shows and health songs and talks with the aid of loud speakers. Films on the Allahabad Kumbh, cholera, tuberculosis, small-pox, malaria, temperance, etc., were screened. These shows are very popular and attracted large crowds every evening.

The Piran Kaliar Fair was held at Roorkee (District Saharanpur) from 4th to 19th June, 1935. The medical and sanitary arrangements were organized by the district medical officer of health, Saharanpur, under the guidance of the assistant director of public health. Only four imported cases of cholera were detected in the fair area. One of these died and the rest were cured. Adequate measures to check the spread of the disease were taken and no more cases occurred.

The next important fair was the Dadri Fair which was held at Ballia from 7th to 22nd November, 1935. The arrangements of the fair were supervised by the assistant director of public health and the district medical officer of health, Ballia. The gathering at this fair on the chief bathing day was over three lakhs. The sanitary and medical arrangements were organized on the lines of the *Magh Mela*, Allahabad. The health of the pilgrims during the *mela* was good and not a single case of infectious disease was detected.

Analysis of railway water-supplies at important railway stations was also carried out during the important fairs and adequate steps were taken to disinfect water-supplies where necessary.

Maternity and child welfare centres.—One child welfare and three new maternity centres were opened during the year. The total number of centres both maternity and child welfare as well as maternity only at the end of the year was 223 (114 rural and 109 urban) and all these were run by the Red Cross. The Cotton Mills, Cawnpore, and the Dayal Bagh, Agra, also maintained one centre each. The maternity and child-welfare work in the rural areas of the province has received an impetus by the opening of nine modified health units.

The total expenditure during the year under report amounted to Rs. 1,47,886. The excess in expenditure was met from the opening balance of the last year. In addition to this, a sum of Rs. 80,000 was spent on maternity and child welfare work by local branches from local subscription, etc.

The number of medical women employed on preventive work in municipalities and other local bodies was 18.

The number of health visitors with diplomas in the municipalities was 10.

One medical woman (L.M.P.) and two Delhi trained health visitors worked in the Provincial Training Centre, Lucknow. One medical woman (M.B., B.S.) and two Lucknow trained health visitors worked in the Health Unit, Partabgarh.

The number of midwives employed was 293.

The training of probationer midwives was, as usual, carried out at the Provincial Training Centre, Lucknow, in domiciliary midwifery and house visiting. Twenty probationers out of 26 passed examinations during March and September and were awarded certificates by the State Medical Faculty, United Provinces, Lucknow.

Facility for midwifery training also existed in the Cawnpore, Maternity and Child Welfare Centre, Dufferin and Mission Hospitals, but these institutions only trained workers for their own needs.

A serious effort was made to train the *dais* throughout the province, specially in 25 maternity and child welfare centres, where medical women or health visitors were employed and in areas under the ten health units in the province.

Six hundred *dais* were trained during the year, of whom 278 were trained in the Partabgarh Health Unit. A sum of Rs. 1,00,000 has been sanctioned from the Silver Jubilee Fund for the building of a health school in Lucknow for the training of health visitors and midwives.

Modified health units were introduced in nine districts during the latter part of the year in connection with rural development work. The scheme in each modified health unit for maternity work consists of—

One health visitor.
Six midwives.
Six trained *dais*.

This work has great possibilities. The rural public is very appreciative of the good and substantial work done by these modified health units.

Correspondence

FOUR MAGGOT-LIKE WORMS REMOVED FROM THE LEFT CONJUNCTIVAL SAC OF A PATIENT

To the Editor, THE INDIAN MEDICAL GAZETTE

Sir,—I am sending you herewith four maggot-like worms removed from the left conjunctival sac of a patient for examination; I hope it will be of interest to the medical profession.

The man experienced severe pain in his left eye at about 2 p.m. on the 10th December, 1936. Next morning at about 8 a.m. when he attended the hospital the lids were found to be oedematous and the conjunctiva congested.

On careful examination two dot-like particles were detected on the upper margin of the cornea and on removal were found to be moving; then two more

were detected and removed. The man felt relieved immediately.

Yours, etc.,
R. GHOSE,
Medical Officer,
Semapur Sugar Works.

P. O. SEMAPUR FACTORY,
DISTRICT PURNIA,
11th December, 1936.

[Note.—No maggots were found in the box received by us from the correspondent; they appear to have been lost *en route*. On the subject of ophthalmomyiasis Dr. D. N. Roy, the assistant professor of entomology at the Calcutta School of Tropical Medicine, comments as follows:—

‘Although cases of ophthalmomyiasis have been occasionally reported from South America, Palestine,

Central Asia, Central Europe, North Africa and Russia, its incidence is by no means common. Almost all the larvæ recorded affecting the human eye belong to *Oestrus ovis*, the common sheep bot-fly. Though the larvæ are normally deposited at the entrance to the nostrils of sheep and subsequently make their way into the nasopharynx, they occasionally deposit one or two solitary larvæ in the vicinity of the human eye and these may either penetrate the mucous membrane of the lid or the lacrymal sac, or may enter the substance of the eye.—*EDITOR, I. M. G.*

A CASE OF PARAPLEGIA AND HYDROPHOBIA FOLLOWING A FULL COURSE OF ANTI-RABIC TREATMENT

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I have read the interesting note on a case of paraplegia and hydrophobia by Dr. S. C. Sen Gupta, D.T.M., published in the November 1936 issue of your journal. The prescription given therein does not appear to be a scientific one to me. In the first instance, potassium iodide is incompatible with liquor strychninæ hydrochloridi, and secondly, putting liquor strychninæ hydrochloridi (an acid preparation) in the same mixture as liquor arsenicalis (an alkaline preparation) comes to doing injustice to their respective reactions. Books on pharmacology seem to be clear on the subject, but since the prescription was passed un commented by you, and being a junior practitioner, I am in doubt. I therefore request that

I may kindly be enlightened in the matter through the medium of your valuable journal.

Yours, etc.,
KESHAV NATH, L.S.M.F.

ANANTNAG, KASHMIR,
14th December, 1936.

[Note.—We are afraid that we overlooked the fact that an incompatible mixture had been prescribed and we stand corrected by this 'junior practitioner'.

Our correspondent does not appear, however, to be so junior that he learnt his pharmacology from the British Pharmacopœia of 1932; he will find in this edition that liquor arsenicalis is a neutral solution.—*EDITOR, I. M. G.*

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I have read with interest a case of hydrophobia reported by Dr. S. C. Sen Gupta in your November 1936 issue.

The prescription with which Dr. Gupta's patient was treated was wrong. It contained three incompatibles; liquor strychninæ is incompatible with potassium iodide and also with liquor arsenicalis.

Yours, etc.,
MUSHARRAFALI,
Medical Officer in charge,
Sadar Hospital.

HAMIRPUR, U. P.,
4th December, 1936.

Service Notes

APPOINTMENTS AND TRANSFERS

THE Secretary of State for India in Council has appointed to the Civil Branch of the Indian Medical Service the following officers of the Indian Medical Service, with effect from the dates stated against their names:—

Lieutenant-Colonel F. J. Anderson, M.C. Dated 28th July, 1935.

Lieutenant-Colonel N. C. Kapur. Dated 15th November, 1935.

Lieutenant-Colonel H. E. Murray. Dated 22nd December, 1935.

Lieutenant-Colonel R. S. Aspinall, C.I.E., an Agency Surgeon, on return from leave is posted as Civil Surgeon, Sibi and Loralai, with effect from the forenoon of the 19th October, 1936.

Major Ajab Singh Garewal is confirmed in the Central Provinces Jail Department, with effect from the 14th August, 1935.

Major G. Verghese is confirmed in the Bihar Jail Department, with effect from the 13th December, 1935.

On reversion from foreign service under the Indian Research Fund Association, Captain J. R. Dogra is appointed as Supernumerary Officer at the Haffkine Institute, Bombay, with effect from the date on which he assumes charge of his duties.

The services of Captain Ilahi Bakhsh are placed temporarily at the disposal of the Government of the Punjab, with effect from the afternoon of the 25th September, 1936.

The services of Captain R. L. Raymond are placed temporarily at the disposal of the Government of Burma, with effect from the forenoon of the 5th November, 1936.

The services of Captain A. E. Kingston are placed temporarily at the disposal of the Government of Burma, with effect from the afternoon of the 11th November, 1936.

Captain G. F. Taylor, an Officiating Agency Surgeon, is confirmed as an Agency Surgeon under the Government of India in the Foreign and Political Department, with effect from the 18th December, 1935.

Captain F. W. Allinson is placed on general duty at the Medical College Hospitals, Calcutta, with effect from the 16th November, 1936.

Captain F. W. Allinson, on general duty at the Medical College Hospitals, Calcutta, is appointed as Civil Surgeon, Midnapore, vice Captain E. G. Montgomery, transferred.

LEAVE

Lieutenant-Colonel J. C. Pyper, O.B.E., an Agency Surgeon, is granted leave on average pay for 8 months combined with leave on half average pay for 4 months, with effect from the afternoon of the 10th October, 1936.

Lieutenant-Colonel R. L. Vance, an Agency Surgeon, is granted, on medical certificate, leave on average pay for 21 days combined with leave on half average pay for 3 months and 9 days, with effect from the 1st November, 1936.

PROMOTION

Majors to be Lieutenant-Colonels

R. Sen. Dated 7th August, 1936.

L. G. Pearson. Dated 18th November, 1936.

P. M. Antia. Dated 23rd November, 1936.

Note.—The promotion of Major S. L. Patney to the rank of Major is ante-dated to 2nd February, 1929. He qualified for accelerated promotion on 13th October, 1936.

The seniority of Lieutenant J. G. Thomson is ante-dated to the 1st May, 1935.

RETIREMENT

Lieutenant-Colonel J. B. Hanafin, C.I.E. Dated 23rd October, 1936.

RESIGNATION

Captain J. D. Gray resigns his commission. Dated 3rd September, 1936.

RELINQUISHMENT

Lieutenant E. N. Brockway relinquishes his probationary appointment. Dated 24th September, 1936.

Notes

ERGOMETRINE B. D. H.

IN 1932 Dr. Chassar Moir published the results of his clinical experiments in which, by a special technique, he had found that the oral administration of aqueous extracts of ergot during the first few days of the puerperium produced remarkable contractions of the uterus within a few minutes. Contractions of equal intensity were not produced after the administration of the pure salts of ergotoxine, and even these less intensive contractions were considerably longer delayed. It was considered, as a result of this work, that the classical effect of ergot administration was after all due to some undiscovered principle and not solely to ergotoxine or any of the alkaloids or amino bodies hitherto isolated.

In March 1935 Drs. Dudley and Moir announced the isolation of a new alkaloid possessing the clinical properties previously described by Moir. This newly-discovered alkaloid has been named Ergometrine by Dudley and Moir.

Simultaneously A. K. Koff and Marvin R. Thompson, by dividing ergot extracts into alkaloidal fractions and non-alkaloidal fractions, found that the quickly-acting substance was contained in the alkaloidal fraction, and that it remained there after the removal of the previously-known alkaloids of ergot. It was considered, therefore, that the immediate contraction that follows the oral administration of certain liquid preparations of ergot is due to some hitherto undiscovered alkaloid of ergot, or at least to some principle contained in the 'residual alkaloid' of ergot.

Thus was provided the key to the solution of the problem which has been the subject of investigation for so many years of the difference between the clinical action of liquid extracts of ergot of rye and of the salts of the pure alkaloid ergotoxine.

Further, as was indicated by the earlier results of Moir, there is a striking difference between the action of ergometrine and the previously-known alkaloid of ergot—ergotoxine. The latter alkaloid, administered in doses of 2 to 3 milligrammes, provokes uterine contractions only after an interval of thirty-five minutes or more, and even these delayed contractions are erratic and somewhat feeble in character. Ergometrine, on the other hand, administered orally in a dose of 0.5 to 1 milligramme causes strong contractions which occur in six and a half to eight minutes after administration. The onset is sudden and accompanied by pronounced uterine spasm, which appears to be caused by a succession of contractions so rapid that the organ as a whole has no time to relax. This stage lasts for about an hour and is followed by a second stage, during which the uterus shows regular, vigorous, isolated contractions, continuing for an hour or more.

It is observed from the foregoing that ergometrine will prove of immense value in obstetrics, particularly on account of the fact that within six and a half minutes of the oral administration of a relatively small dose of it there is produced with unfailing regularity the same effect as that which hitherto has been obtained with so much uncertainty by the administration of the variable liquid extract of ergot.

Thus ergometrine provides that long-felt desideratum—an ergot preparation which acts rapidly and can be safely administered immediately after parturition.

Ergometrine B. D. H. is now available for the use of obstetricians and of general practitioners for oral administration in the form of tablets each containing 0.5 milligramme of the pure alkaloid.

For administration to patients who may still be under anaesthesia or who may be too ill to retain any medication administered by the mouth, Ergometrine B. D. H. is issued in solution in ampoules for intramuscular injection and for intravenous injection. In administering Ergometrine B. D. H. by injection the intramuscular

route is usually employed, the intravenous route being reserved for very urgent cases in which a maximum response is required in a minimum of time.

ADRENALIN VAPORIZER AND ADRENALIN CHLORIDE SOLUTION 1 : 100

MESSRS. PARKE, DAVIS AND COMPANY have put on the market the above vaporizer and adrenalin chloride solution 1 : 100 for the inhalation treatment of bronchial asthma.

By this means we have a method of promptly relieving paroxysms without resorting to hypodermic injections.

This new method first reported by Graeser and Rowe (*Journal of Allergy*, 6 : 415, 1935), is based on the administration of a special solution of adrenalin chloride solution 1 : 100 by means of an adrenalin vaporizer. The results obtainable from the oral inhalation of this solution have been uniformly successful. Inhalation of the vapor-like spray of adrenalin 1 : 100 rarely causes the side effects, such as nervousness, tachycardia and other circulatory symptoms which may follow hypodermic administration of adrenalin solution. This treatment avoids the discomfort and inconvenience of injection and can be applied by the patient at home after detailed instructions have been given by the physician.

Further particulars may be obtained from Messrs. Parke, Davis and Company, P. O. Box 88, Bombay.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

RADIOLOGICAL AND LABORATORY INVESTIGATIONS OF CHRONIC GASTRO-INTESTINAL DISTURBANCES IN THE TROPICS

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.),
M.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

Honorary Physician to H. M. the King

R. T. M. HAYTER
Resident Medical Officer

and
S. N. BHATTACHARYA, M.B., D.T.M.
Registrar

(From the School of Tropical Medicine and Carmichael Hospital for Tropical Diseases, Calcutta)

CLINICIANS in the tropics admit the existence of a group of chronic 'bowel' conditions in which a definite diagnosis cannot be made by the ordinary methods of examination. The majority of the patients belonging to this group have suffered in the past from chronic dysentery, either bacterial or protozoal in origin, and show diverse and often vague symptoms such as indefinite pains in the abdominal region, indigestion, flatulence, irregularity of the bowels, etc. In a number of them non-lactose-fermenting organisms such as *Bact. pseudo-carolinus*, *Bact. asiaticus*, *Salmonella morgani* are detected; in others cysts of *Entamoeba histolytica*, Charcot-Leyden crystals, flagellates such as *Giardia intestinalis* or *Trichomonas hominis* are found; in others helminthic parasites are discovered in the stools. Although it is natural at first to attribute the patients' symptoms to the particular infection found, it has been often observed that symptoms in many do not abate in spite of the eradication of such infections. The disturbances in these patients are, therefore, often put down as functional in nature or a vague term such as 'chronic dyspepsia' is used in their diagnosis. On going into the history of these patients it will be found that they are chronic sufferers who have been treating themselves with 'stomach powders', 'liver pills', 'salts', and have even received courses of emetine from their medical attendants, but with little or no permanent relief or benefit. The trouble goes on for years and some of them are described by their medical attendants as suffering from neurasthenia, a term used to cloak our ignorance in the tropics as often as anywhere else. We believe, that there is no such condition as neurasthenia without a definite organic lesion of some kind which is the source of irritation in some part of the body. The intensity of the symptoms produced varies with the degree of sensitiveness of the individual to the irritative stimuli from this source. The symptoms thus produced are reflex in origin and the sufferings of the individual may sometimes be severe, but frequently there may be

periods of intermission, when the patient feels comparatively well and may even think he is cured. A careful clinical examination of these patients shows that the classical textbook signs and symptoms of a definite gastro-intestinal lesion are, as a rule, absent. Some of them have been shown to have definite surgical lesions which are likely to be overlooked in ordinary examination. Such patients are seldom thoroughly enough investigated for a proper diagnosis to be aimed at even in hospitals, to say nothing of the private practitioners, as laboratory facilities for such detailed investigation are often not available. These patients, therefore, go on suffering for years till anæmia, emaciation or other complications and sequelæ supervene.

During recent years the senior author has had under his care a series of such cases in the Carmichael Hospital for Tropical Diseases, that were thoroughly investigated from every aspect. Besides detailed and thorough bacteriological and protozoological investigations, examination by x-rays after an opaque meal is essential in many of these cases to locate the lesion, and in this paper we give the result of the analysis of 80 patients in which this procedure was adopted.

Before discussing the results of the radiological examination we intend to go a little more into the symptomatology of these patients. As stated before, the symptoms were mostly of a subjective nature and they might be classified under three main heads, namely, abdominal pain and tenderness, gastric symptoms and intestinal symptoms.

(1) *Abdominal pain*.—Out of 80 patients 43 complained of pain in some part of the abdomen. A large number of the patients, 18 in this series, complained of pain in the epigastrium, nine had pain in the cæcal region and 16 in other parts of the abdomen. Three patients had definite hunger pains and three others complained of gripping and tenesmus such as are seen in acute dysentery. On palpation, tenderness and rigidity of muscles were elicited in 19 patients and out of these 11 had it in the region of the cæcum and ascending colon, five in the left side of the abdomen and three in the epigastrium. The large bowel showed thickening in some of them.

(2) *Gastric symptoms*.—These consisted chiefly of a feeling of heaviness after meals, heartburn, acid eructations, loss of appetite, nausea and occasional vomiting. Thirty-six patients in this series suffered from one or other of these symptoms.

(3) *Intestinal symptoms*.—Irregularity of the bowels was one of the main symptoms for which the patients sought admission into the hospital. Constipation occurred in 20, diarrhœa in 23, and constipation alternating with diarrhœa in 13. A large proportion of patients, as many as 23, passed mucus and ten passed mucus and blood

in their stools. Two patients had melæna and two occult blood in their stools. Flatulent distension was a common feature in 30 patients and often it was most distressing, the patient getting 'blown up' and the heart being secondarily affected by pressure.

The main radiological findings may be summarized as follows :—

(1) In one group, irregularity of the outline of the duodenal cap, pyloric spasm and filling defects were frequently seen, and in a few cases definite craters with barium content were found several hours after the stomach was empty. Duodenal distension with spasm and catarrh was often seen. Some of these patients undoubtedly had duodenitis and others showed signs of active or healed ulcers. In one patient, not included in this series, we found a diverticulum in the region of the duodenum.

We may also note here a condition which was not infrequently met with in a number of the patients and that was hurrying of the meal through the small intestines. In a few hours

transverse colon all seemed to be lying in the pelvis.

(5) In the fifth group there were definite signs of inflammation or ulceration in some part of colon, accompanied by excessive gas formation. In others there was abnormal irritability of the large gut and residual strings or streaks of barium were visible.

Classified according to what was considered to be the main radiological diagnosis, the patients could be grouped as follows :—

(1) Duodenal ulcer and duodenitis ..	16
(2) Pathological appendix ..	21
(3) Stasis of the intestine ..	26
(4) Atony of the gastro-intestinal tract	32
(5) Ptosis	7
(6) Catarrh	13
(7) Colitis	4
(8) Normal	13

The patients rarely suffered from any one of these conditions singly, a combination of these being the rule. The details are given below in a tabular form.

TABLE

the meal passed through the small gut, and reached the hepatic or the splenic flexure.

(2) In another group, the appendix was visualized for long periods, that is up to 72 hours after the meal—sluggish appendix. It was sometimes abnormally long, was distended, had constrictions in it, showed the presence of concretions and was often adherent to the cæcum. Such cases were classed as pathological appendix. The cæcum was frequently mobile and showed signs of ulceration or catarrh, which sometimes extended all the way down to the pelvic colon. Thickening and spasm of the colon were frequently seen.

(3) In the third group, abnormal delay in emptying, distension of the cæcum and the colon, often with marked visceroptosis, diverticulitis, stagnation of the contents and catarrh were the main features. In some of the cases the colon still retained the meal after 48 hours or longer. These cases were classified as intestinal stasis.

(4) In the fourth group, loss of muscular tone of the wall of the whole of the gastro-intestinal tract was seen and there was abnormal retention of contents. In some, visceroptosis was marked; the stomach, the small intestines and the

The various symptoms in relation to the different radiological findings will be better understood from the following descriptions :—

Pain.—Of the 16 patients in whom signs of ulceration were visible, only three had definite hunger pains. Six patients had pain in the epigastrium, without any definite relation to food. Two patients who complained of pain in the right iliac fossa also had pathological appendix. Some of these patients underwent operation and the diagnosis was confirmed. In those who had intestinal stasis, pain was a common symptom. Out of 20 cases in this series, 14 had it in some part of the abdomen. Of the ten patients who showed signs of atony of the gut only three, i.e., those in whom ptosis was present, complained of pain, which was confined to the upper part of the abdomen.

Gastric symptoms.—Out of 80 patients, 36 had symptoms referable to the stomach. Of these, 13 were found to be suffering from some lesion in the duodenum. When intestinal stasis was present gastric symptoms were also a common feature.

Intestinal symptoms.—Flatulent distension of the abdomen, constipation or constipation

alternating with diarrhoea, was a common feature among those patients in whom the skiagrams revealed a condition of loss of tone or a condition of intestinal stasis due to spasmodic contraction of the large gut. Out of the total 80, 23 had looseness of the bowels; as might be expected many of these had colitis and catarrhal condition of the bowels, but quite a number, seven in this series, showed involvement of the appendix and were diagnosed as pathological appendix. Banerji, Chopra and Ray (1936) have fully discussed these cases elsewhere. What we wish to stress here is that in those patients in whom the appendix was not cleared of the opaque meal after 24 hours (sluggish appendix) while the cæcum and ascending colon were empty, a pathological appendix was suspected, and those in which the appendix still retained the meal after 48 hours and longer a definite diagnosis of pathological appendix could be made. These results were confirmed by operation in a number of cases.

Thirty-three patients passed mucus in their stools, being generally those whose stools were diarrhoeic, though there were a few who passed streaks of mucus with constipated stools. Mucus was frequently observed in the stools of those in whom the appendix was pathological; it also occurred in those who had colitis and atonic or spastic conditions of the gut. Those who had acute colitis often passed both mucus and blood in their stools. The only case of duodenal ulceration that passed mucus and blood had an *E. histolytica* infection.

Of the patients who gave a history of melæna, one showed signs of duodenal ulceration, which was confirmed by radiological examination. In the other cases, no lesion was detected in the gastro-intestinal tract. The two cases with occult blood had heavy hookworm infections.

Anæmia was a common symptom in this series, 22 patients suffered from it. Of the four patients who showed a rise of temperature above normal while in hospital, two had malaria. The liver was enlarged in five cases of which three had *E. histolytica* infection.

A detailed microscopical and cultural examination of the stools was done in all this series. Five patients were found to be suffering from hookworm infection. *E. histolytica* was found in the stools of eight patients.

The bacterial organisms of doubtful pathogenicity, which were found in the stools by culture, are given below:—

Summary

A series of 80 cases with chronic gastro-intestinal disturbances admitted under the senior author were investigated by radiological examination. Many of them originally had dysentery, which was later complicated with other pathological conditions of the bowels. Symptoms were variable, the chief being abdominal pains, distressing flatulence and irregularity of the bowels, which had lasted for prolonged periods and which were not controlled by ordinary methods of treatment. This is the class of case which often comes under the category of functional or neurasthenic. Nothing but a thorough laboratory and radiological examination could have diagnosed these cases. The commonest cause was stasis and atony in 37.5 per cent in this series. Other causes were pathological appendix, duodenal ulceration, and colitis, in the order of frequency. Thirteen patients showed normal appearance of the gastro-intestinal tract.

It was observed that in patients in whom the appendix still retained the barium meal after 24 hours the organ was not normal. In those in which the meal was still retained after 48 hours the appendix was definitely pathological and many of these cases showed constrictions and concretions. These observations were confirmed in a number of patients after operation.

REFERENCE

Banerji, L. M., Chopra, R. N., and Ray, P. N. (1936). Amoebiasis and Appendicitis. *Indian Med. Gaz.*, Vol. LXXI, p. 693.

that neither of these drugs has any effect on the viability of the gametocytes of *Plasmodium falciparum*. In fact, the administration of quinine in some cases brings about an increase in the number of crescents in the peripheral blood. The necessity for a drug, possessing crescenticidal properties has therefore been felt for a long time. It was thus a great event when the synthesis of plasmochin was carried out by Schulemann and his co-workers in 1926. The literature regarding the action of this drug is enormous and there is no doubt that it produces a marked and rapid destructive action on the gametocytes of *P. falciparum*.

Knowles and Das Gupta (1931) worked out the minimal lethal dose of plasmochin for the gametocytes of the Indian strains of *P. falciparum*. They have shown that a total dosage of 0.04 gm. to 0.06 gm. of the drug is sufficient to eradicate all the sexual forms from the peripheral blood, even when the infestation is a very heavy one. These conclusions have also been borne out by Clemesha (1933). This dosage should be administered by the mouth, giving 0.01 gm. of the drug twice daily for two to three consecutive days. Within 24 hours of administration of plasmochin the gametocytes swell up and become irregular, the chromatin breaks up by karyorrhexis and the crescent stains very badly. In 48 hours, many of the gametocytes present in the film are almost unrecognizable and they finally disappear from the peripheral circulation.

In the literature, few cases of resistance to plasmochin are on record. In the Carmichael Hospital for Tropical Diseases we have had opportunities of treating and observing carefully a large number of patients with *P. falciparum* infection showing gametocytes in their blood, and we have found that the total dosage of 0.04 gm. of plasmochin as a rule succeeded in eradicating the gametocytes altogether from the peripheral blood, however large their number may be. Only in a few instances was a dosage of 0.06 gm. necessary.

We were therefore somewhat surprised when, in a patient recently admitted under the senior author into the Carmichael Hospital for Tropical Diseases and showing a heavy infection with the sexual forms of *P. falciparum*, the crescents persisted even after administration of 0.095 gm. of plasmochin, and a total of 0.135 gm. had to be given before they disappeared from the peripheral blood. This patient belonged to the series in which we were testing the effect of combined atebirin and plasmochin dragées (Bayer) on the Indian strains of malaria, and the details of this case are as follows :

Case I.—S. M. K., aged 31, was admitted into hospital on 3rd September, 1936, with the history of malarial fever off and on for the last three months. He was emaciated, slightly jaundiced and his spleen was palpable about an inch below the costal margin. Examination of the blood revealed the presence of

malignant tertian rings and crescents. The laboratory findings and treatment are described below:—

Date	Laboratory findings	Treatment
4-9-36	Scanty M. T. rings and crescents.	
7-9-36	Do.	Atebrin 0.1 gm. and plasmochin 0.005 gm., t.d.s.
8-9-36	Crescents	Do.
9-9-36	Do.	Do.
10-9-36	Do.	Do.
11-9-36	Do.	Do.
12-9-36	Scanty crescents	..
13-9-36	Do.	..
14-9-36	Do.	..
15-9-36	Do.	..
16-9-36	Do.	Plasmochin 0.01 gm., b.d
17-9-36	Do.	Plasmochin 0.02 gm., b.d
18-9-36	Nil	..

Laboratory examination.—Aldehyde test—negative; antimony test—undiluted + and diluted (1/10) —; levulose tolerance test—normal before and after treatment with the combined preparation of atebirin and plasmochin; van den Bergh test—direct —, indirect ±, before and after treatment. Stool examination showed the presence of *Trichomonas hominis*, *E. nana* cysts, *Bact. morgani* and *Bact. para-asitacus*.

The drug was administered by the mouth in the form of tablets each containing 0.1 gm. of atebirin and 0.005 gm. of plasmochin three times a day. The results puzzled us a good deal at first. We then started testing the urine for the presence of these drugs in order to see if any absorption was taking place. There was no difficulty in testing the presence of atebirin but we found the detection of plasmochin was not so easy. In a series of cases in which dragées were given, the urine was tested as a routine for the presence of atebirin, and parasites in the peripheral blood were also examined daily with a view to seeing what effect was being produced on them. Our intention in describing these cases is to bring out the fact that the question of absorption and excretion is an important factor in drug therapy and should never be lost sight of in cases where the expected results are not attained. Plasmochin is a toxic drug and as, in the case described, no such symptoms were noticed even with a dose much higher than the ordinary therapeutic dose, it is likely that the normal absorption of the drug was interfered with.

Case II.—A. U. S., aged 16, was admitted into hospital with the history of malarial fever for three months. He was anæmic and slightly emaciated and the breath

sounds were slightly diminished on the back. He gave a history of chronic irregularity of the bowels and occasional attacks of epistaxis. His spleen was tender and palpable about 2½ inches below the costal margin. Examination of the blood revealed the presence of scanty malignant tertian rings.

Date	Malaria parasites	Treatment	REMARKS
21-11-36	Scanty M. T. rings.	Atebrin 0.1 gm. and plasmochin 0.005 gm., t.d.s.	Urine shows no atebrin. No effect on temperature.
22-11-36	Do.	Do.	
23-11-36	Do.	Do.	
24-11-36	Do.	Do.	
25-11-36	Do.	Do.	
26-11-36	Do.	Atebrin 0.1 gm., t.d.s.	Urine: appreciable amounts of atebrin. Do.
27-11-36	Do.	Do.	
28-11-36	Do.	Do.	
29-11-36	Very scanty M. T. rings.	Do.	
30-11-36	No parasites	Do.	
1-12-36	Do.	..	

Other laboratory findings.—Hookworm 700 eggs per c.cm.; urobilin present in the urine; van den Bergh indirect +, direct —; R. B. C. 3,300,000; hæmoglobin 62 per cent.

It will be observed that after a full five days' course of the atebrin and plasmochin dragées the asexual forms still persisted and the urine did not show the presence of atebrin. The patient was then put on atebrin by itself to see if the combination was at fault. The drug was detected in his urine in small quantities, and the asexual parasites disappeared from the peripheral circulation. The patient suffered from chronic gastro-intestinal trouble and had hookworm infection. It would appear that whereas the drug from the combination dragées was not absorbed at all in this case, atebrin by itself was absorbed with difficulty.

Case III.—K. N., aged 15, was admitted into hospital with the history of malarial fever for five months. He was anæmic, slightly icteroid and his spleen reached the level of the umbilicus. Examination of the blood showed the presence of a moderate infection of benign tertian malaria.

Date	Malaria parasites	Treatment	REMARKS
25-11-36	B. T. rings, trophozoites.	Atebrin 0.1 gm. and plasmochin 0.005 gm., t.d.s.	Urine: no atebrin.
26-11-36	Do.	Do.	
27-11-36	Do.	Do.	
28-11-36	B. T. rings, trophozoites, gametocytes—scanty.	Do.	

Date	Malaria parasites	Treatment	REMARKS
29-11-36	B. T. rings, trophozoites—scanty.	Atebrin 0.1 gm. and plasmochin 0.005 gm.	No effect on temperature.
30-11-36	Urine: no atebrin.
1-12-36	B. T. rings, trophozoites—scanty.	Atebrin 0.1 gm., t.d.s.	Do.
2-12-36	Do.	Do.	Urine: atebrin in small amount.
3-12-36	Do.	Do.	Urine: atebrin in appreciable amount.
4-12-36	No parasites	Do.	Do.
5-12-36	Do.	Do.	Do.
7-12-36	Do.	..	Do.

Other laboratory findings.—Hookworm less than 100 eggs per c.cm.; urobilin present in urine; van den Bergh indirect +, direct —; Widal: typhoid (H) 25, paratyphoid A (H) + 50; Wassermann reaction moderately positive.

In this patient the usual doses of atebrin and plasmochin in the form of dragées had no effect on the parasites in the blood. No atebrin could be detected in the urine. Even after administration of atebrin alone the absorption of the drug, as judged from excretion in urine, was slight at first. The patient had light hookworm infection and was anæmic.

Case IV.—G. A. G., aged 29, was admitted with the history of malarial fever for two weeks. He suffered from an attack of enteric fever in 1923; his liver was tender, the spleen was palpable about half an inch below the costal margin and a few moist sounds were also audible at the back of the lungs. Examination of the blood showed a scanty malignant tertian infection.

Date	Malaria parasites	Treatment	REMARKS
8-10-36	Scanty M. T. rings.	Atebrin 0.1 gm. and plasmochin 0.005 gm., t.d.s.	Urine: no atebrin.
9-10-36	No parasites	Do.	
10-10-36	Do.	Do.	
11-10-36	Do.	Do.	
12-10-36	Do.	Do.	
13-10-36	Very scanty B. T., growing trophozoites.	..	Urine: appreciable amount of atebrin.
14-10-36			
15-10-36			
18-10-36	B. T. rings, growing trophozoites.	Atebrin 0.1 gm., t.d.s.	
19-10-36	Do. scanty	Do.	
20-10-36	Do.	Do.	
21-10-36	No parasites	Do.	
22-10-36	Do.	Do.	

Other laboratory findings.—R. B. C. 3,490,000; hæmoglobin 70 per cent; Wassermann reaction strongly positive; van den Bergh: indirect—faintly positive, direct—negative.

This patient did not show any gastro-intestinal trouble, yet no atebtrin was detected in the urine after administration of the combined dragées for five days. But when plain atebtrin was started the urine showed appreciable amounts of the drug.

Case V.—S. C. S., aged 37, was admitted with the history of an attack of malaria about two months back. Eleven days after admission into the hospital, the patient started getting fever and, on examination of his blood, a fair number of malignant tertian rings was found. He was suffering from palpitation and difficulty of breathing and gave a history of occasional attacks of hæmatemesis. His spleen was just palpable.

Date	Malaria parasites	Treatment	REMARKS
3-11-36	M. T. rings	Atebrin 0.1 gm. and plasmochin 0.005 gm., t.d.s.	
4-11-36	Do.	Do.	No effect on temperature.
5-11-36	Do.	Atebrin 0.1 gm., t.d.s.	Urine: trace of atebtrin.
6-11-36	Do.	Do.	
7-11-36	Very scanty M. T. rings (thick film).	Do.	
8-11-36	No parasites.		

Other laboratory findings.—Hookworm, 3,800 eggs per c.cm.; *E. nana* cysts in stools; urobilin present in urine; van den Bergh: indirect +, direct—.

This patient suffered from a moderate infection with hookworm and showed no atebtrin in the urine after administration of the combined dragées for two days. Atebrin by itself was absorbed with difficulty, as only traces were found in the urine, but the parasites disappeared from the peripheral blood on the fourth day.

Case VI.—N., aged 26, gave history of fever for six days only. Blood showed benign tertian infection. He gave a history of chronic constipation.

Date	Malaria parasites	Treatment	REMARKS
25-10-36	B. T. rings, growing trophozoites and schizonts.	Atebrin 0.1 gm. and plasmochin 0.005 gm., b.d.	
26-10-36	Do.	Do.	
27-10-36	Do.	Do.	No effect on temperature.
28-10-36	Do.	Quinine.	
29-10-36	Scanty B. T. rings, growing trophozoites.	Do.	
30-10-36	No parasites	Do.	
31-10-36	Do.	Do.	
1-11-36	Do.	Do.	Urine: no atebtrin.
3-11-36	Do.	..	Do.
4-11-36	Do.	..	Do.

Other laboratory findings.—*Bact. pseudo-carolinus* and *Ps. pyocyanea* present.

In this patient the combination dragées had no effect and administration of quinine caused disappearance of the parasites and symptoms were controlled. No atebtrin could be detected in the urine. The stools of the patient showed the presence of organisms of the metadysentery group. This is the class of case in which the gastric acidity is usually low and the meal rushes through the small intestine.

Case VII.—H., aged 30, was admitted with the history of malaria—off and on—for three years. He was treated outside with quinine, esanofele, etc., but without much effect. His spleen was just palpable and blood showed scanty benign tertian infection.

Date	Malaria parasites	Treatment	REMARKS
	B. T. rings and growing trophozoites—scanty.	Atebrin 0.1 gm. and plasmochin 0.005 gm., t.d.s.	
	Do.	Do.	Urine: atebtrin a trace.
	Do.	Do.	Urine: no atebtrin.
	Do.	Do.	Urine: just a trace of atebtrin.
	Do.	Do.	

Other laboratory findings.—*Trichomonas hominis* and *Bact. pseudo-carolinus*.

In this patient, after administration of combination dragées, only a minute trace of atebtrin could be detected in the urine and the parasites and symptoms persisted. The stools showed the presence of organisms of the metadysentery group. It is the class of case in which the meal rushes through the intestine and the urine only shows a trace of atebtrin when it was given either in the form of combination dragées or by itself.

Discussion

Variations in the effectiveness of drugs and relative resistance of certain strains of malarial parasites have been frequently reported. What we wish to show, by describing these cases, is that absorption and excretion of drugs are important factors and should not be lost sight of when expected results are not forthcoming. The same drug, given to two different patients under similar conditions for the same symptoms, has behaved entirely differently, and, on testing the urine, one showed the presence of the drug while the other did not.

The reason of this variability in absorption is not far to seek. An analysis of the records of patients admitted into the Carmichael Hospital for Tropical Diseases during the year 1935 shows that in as many as 60 per cent of the patients the gastro-intestinal tract was involved.

Detailed investigation with the help of laboratory and x-ray examinations brought out the fact that approximately 26 per cent suffered from helminthic infections, 28 per cent from catarrhal conditions of the intestines of various origin and the remaining patients from pathological appendix, gastro-duodenal ulcer, pathological gall-bladder, etc. Helminthic parasites, especially hookworm, live in the upper part of the small intestine and a heavy infection may alter the normal physiological processes of absorption in this part (cases II and V). In addition, a large number of patients complained of vague abdominal symptoms without showing any definite laboratory findings for known infective agents. Most of these patients showed a condition of hypo- or hyper-chlorhydria which is very commonly associated with chronic dysenteries and colitis in which the original causal agent, either bacterial or protozoal, is very difficult to detect. The acidity of the stomach is in itself a factor in the absorption of the drug inasmuch as it is often here that the drug is rendered suitable for absorption by disintegration of tablets and conversion of insoluble into soluble compounds.

Another important factor which should not be lost sight of is that the rapid passage of the drug through the small intestine, where absorption of a drug usually takes place, occurs in chronic diarrhoeas and dysenteries. X-ray examinations by barium meal show that the meal in these cases hurriedly passes through the small intestine and in a few hours, less than five usually, it reaches the pelvic colon, not a trace being left in the small intestines. The drug is thus not allowed time for absorption. Besides these conditions, the mucous membrane of the gastro-intestinal tract is not quite normal in a large percentage of patients in the tropics and peptic ulcers, pathological gall-bladder and appendix are frequently met with. The absorption of drugs in such cases may not be normal.

Summary

The following factors may be responsible for the variability in the absorption of drugs from the gastro-intestinal tract and the practitioner in the tropics should bear them in mind when the expected therapeutic results are not obtained :—

(1) The acute or chronic inflammatory condition of the mucous membrane. It is well known that under such conditions absorption of drugs is modified.

(2) The rapid passage of the meals through the small intestines generally, and upper part of the small intestine particularly, where absorption of these drugs usually takes place.

(3) The hypo-acidity of the stomach which is often met with in chronic dysenteric infections.

THE TREATMENT OF PITYRIASIS ROSEA

By P. A. MAPLESTONE, D.S.O., D.Sc., M.B., B.S., D.T.M.
and

N. C. DEY, L.M.P., L.T.M.

(From the Medical Mycology Inquiry, School of Tropical Medicine, Calcutta, partly financed by the Indian Research Fund Association)

THE ætiology of pityriasis rosea is still unknown and there are several theories as to its cause. The most recent of these is that the disease is caused by a filtrable virus, and as the work described in this paper was undertaken solely with the object of testing this theory it is the only one that will be considered.

Wile (1927), as the result of several years' observation amongst a large body of university students, has produced some facts that suggest that pityriasis rosea is contagious, and after many failures he partially succeeded in transmitting it to himself and three other volunteers. He employed fluid from a blister raised over a typical lesion, in two of the cases it was injected intradermally and in two it was applied to a scarified surface. The eruption produced was very mild and short-lived in every instance but some of the lesions definitely resembled those of pityriasis rosea.

Thomson and Cumings (1931) made a complete pathological investigation of the disease

(Continued from previous column)

(4) Lastly, the drug may be administered in the form of tablets which are not properly constituted. Some of the ingredients used may prevent the disintegration of the tablet before reaching the part where absorption of the drug takes place, and in some cases the tablets may not disintegrate at all and may pass through the gut in an unbroken mass. It is open to question whether the atebirin and plasmochin combination in the dragées used renders the absorption of the individual drugs more difficult. It will be observed that, in a number of cases cited, atebirin was not absorbed when the combination dragées were administered, whereas atebirin in the form of tablets by itself was absorbed.

and they obtained suggestive positive skin reactions, working on lines similar to those used in the Dick reaction, by the employment of a filtrate of scales from the lesions. They also tried to produce the disease by intradermal injection of blister fluid after Wile's method. Altogether, twenty healthy persons and five with other skin diseases were tried in these two experiments and none of them contracted the disease. In spite of these negative results, after careful consideration of all the facts, these two workers consider that pityriasis rosea has some connection with the exanthemata and is probably caused by a filter-passing virus. They explain their failures on the ground that it is an organism to which the majority of people are refractory, and it is pointed out that Wile's partial successes were achieved by inoculation from cases of unusual severity, which suggests a strain of more than usual virulence.

After a very full discussion of all the theories, old and new, which it is not considered worth repeating here, Lord (1932) came to the conclusion that pityriasis rosea is feebly infectious, the causative organism is unknown and the portal of entry is the herald spot.

There are several skin diseases that are now generally accepted as being caused by filtrable virus and amongst these are molluscum contagiosum and infective warts. Ghosh (1934), in the case of molluscum contagiosum, and Ghosh and Maplestone (1935), in the case of warts, working at the Calcutta School reported favourable results in the treatment of these diseases by injection with filtered carbolic emulsion of material taken from the skin lesions and presumably containing the killed virus. On this account it was decided to try the same form of treatment in pityriasis rosea.

Method of preparing the lysate.—A recently-erupted spot of moderate size (1 to 1½ cm. in diameter) is selected and thoroughly cleaned with a mixture of alcohol and ether in equal parts. The spot is then anæsthetized by injection beneath it of 2 per cent novocaine solution. An incision is made with a sharp knife completely surrounding the lesion but care is taken not to involve any healthy skin in the circle. The portion outlined by the incision is dissected out, and the whole depth of the cutis vera is removed along with the epidermis, but care is taken not to include any subcutaneous fat. The wound is closed by one or two horse-hair sutures and an appropriate dressing applied.

The portion of skin is placed in a sterile test tube and weighed by difference, the weight of the empty test tube having first been ascertained. The tissue is washed in normal saline solution and this is poured away to remove as much blood as possible and it is placed in an agate mortar with sterile pumice powder and thoroughly ground up. Normal saline is gradually added during the process until an

amount representing 1 c.cm. of saline to each 10 mgm. of tissue has been added. When the emulsion appears homogeneous it is filtered through a Chamberland L3 candle into a vaccine bottle and an amount of 0.2 per cent formalin* or 1 per cent carbolic in saline is added, the amount being equal to the amount of the filtrate. After being tested for sterility the filtrate so prepared is used for injection.

Dosage.—The initial dose we used was 0.1 c.cm. and this is increased by 0.1 c.cm. for every succeeding dose until a maximum of 0.5 c.cm. has been reached, in the case of adults. For children the same initial dose was given but the maximum was only 3 c.cm. It is probable that larger doses could be given for in one case (no. 14) larger doses were tried to see if they were more efficacious than the smaller ones and no unpleasant reactions were noted but, as they apparently were no better than the smaller doses, they were not repeated in other cases. Injections were given every three or four days if the patients attended regularly; it will be noted in the protocol that this interval was considerably exceeded in some instances, but only because the patients did not come on the proper days. We found no difference in results of treatment whether an auto-lysate or a stock lysate pooled from a number of patients was used.

The particulars of the cases and results of treatment are given in tabular form. Nothing of special interest emerges from these records regarding the ætiological characters of the cases studied. It will be seen that the majority of the patients are older children or young adults, which is the same age incidence as has been noted elsewhere. The males are in great preponderance over the females but this is in no way significant for the numbers of males attending the department are much greater than those of the females. The same thing is found when caste and race are considered for the apparently much greater number of Hindus than of Mohammedans is explained when it is noted that the average attendance of the former for all diseases is about four times that of the latter, and people of European descent are relatively rare in our clinic, which fact accounts for the few persons of this category in our series. From these observations it may be concluded that pityriasis rosea in India shows no epidemiological differences from those seen in other parts of the world where the disease has been studied.

Although no detailed investigation regarding other possible causes of the disease was made the opportunity was taken to examine all of our patients for the presence of fungi in the lesions, because one of the theories of the causation of

* Formalin was soon given up as it was found very painful, even in the strength of 0.1 per cent in which it was used, whereas 0.5 per cent carbolic is painless, so it is now always employed.

the disease is that it is a fungus infection. Only one of our cases showed any fungus at all and he said he had been suffering with tinea cruris of the groins for many years. Although the fungus theory has few supporters at the present day our results, in a country where all kinds of skin disease from fungal infection flourish, lend strong support to the view that it has nothing to do with the causation of pityriasis rosea.

Pityriasis rosea is a self-limiting disease and it usually disappears spontaneously in six to eight weeks from the first appearance of the herald spot and about four weeks after it has become generalized, though there are a few instances where it persists for months. It is therefore rather difficult to assess with any degree of accuracy the value of our form of treatment. The facts that most of our cases, that had persisted for two months or longer, cleared up fairly rapidly after beginning injections and that about half the cases lasted less than four weeks from the time the herald spot appeared are suggestive that the treatment lessens the duration of the disease. An attempt was made to check our results by means of controls selected at different

times during the investigation; these were given nothing but calamine liniment to apply. Unfortunately none of these controls continued to attend for more than a fortnight although there was no sign of the disease improving. It is probable that they were dissatisfied at not receiving as much attention as the others who were getting injections. Injection treatment is remarkably popular in India and one is repeatedly being asked by patients to employ it for all imaginable diseases, and refusal to do this often causes obvious disappointment and dissatisfaction.

Relapse or a second attack of pityriasis rosea is not common, but it occurred in two of our series. In one the rash returned two months after its apparent cure, and in the other six weeks afterwards. Both these second attacks were generalized from the beginning and there was no herald spot.

It is not claimed that our results are sufficiently definite to prove by specific injections that the disease is caused by a filtrable or other organism, but we do consider they lend strong support to this idea, which is gradually gaining ground amongst dermatologists.

HODGKIN'S DISEASE OF THE PEL-EBSTEIN TYPE: SOME UNUSUAL FINDINGS

By L. EVERARD NAPIER, M.R.C.P. (Lond.)

Acting Professor of Tropical Medicine

R. N. CHAUDHURI, M.B. (Cal.)

Assistant Professor of Tropical Medicine
and

P. C. SEN GUPTA, M.B. (Cal.)

(From the Calcutta School of Tropical Medicine)

HODGKIN'S DISEASE is not very frequently encountered in this country, though the incidence is probably about the same as it is in England. The following case is reported in some detail as it exhibited unusual features:—

An Anglo-Indian boy, aged 12 years, was admitted to the Carmichael Hospital for Tropical Diseases on the 25th June, 1936, with a history of periodical bouts of fever since September 1935, that is, for nine months.

In October 1935, he was admitted to the Presidency General Hospital and diagnosed clinically as a case of kala-azar. He was given a course of antimony injections; the temperature came down and he was discharged as cured.

Next month he had another attack of fever and was readmitted to the same hospital, but by the time he arrived in the hospital the temperature had already come down. As he was anæmic he was given a course of campolon and discharged about the end of December. The boy kept fairly well during January 1936, but during the next four months he had three bouts of fever and was treated in the railway hospital. As the febrile relapses could not be stopped, he was sent to this hospital.

On admission, the patient was afebrile. He was anæmic, and his complexion was pale and yellow; this was assumed to be due to atabrin he had taken outside. The spleen was enlarged $1\frac{1}{2}$ inches and liver $\frac{3}{4}$ inch below the costal margin. There was a functional systolic bruit in the heart. A few glands were palpable in the neck and groins; these were small, discrete and painless. No abnormality was detected in any other system.

After eight days' stay in the hospital he developed fever which gradually increased; the temperature varying from 102°F. to 104°F. The spleen was enlarged 3 inches below the costal margin, and was soft but not tender. The pulse was rapid (140 per minute). He had slight bronchitis. There was no toxæmia. He was given expectant treatment, viz, quinine, diaphoretics, digitalis, glucose, etc. The temperature came down by lysis after 18 days.

The boy remained afebrile for the next ten days except for a slight rise in temperature towards the latter part of this period. The spleen rapidly diminished till it was just palpable. In view of the past history and the finding of some suspicious bodies in the spleen puncture smear neostibosan injections were started on the 22nd July; a course of 12 injections (daily) amounting to a total of 2.3 grammes was given.

On the 30th July the patient had another bout of fever, the second since his admission. It was of the same type as the first one and was associated with splenic enlargement and tachycardia; the temperature came down on the thirteenth day. Towards the end of this period he had local inflammation in the throat. The glands in the neck were considerably swollen and tender. In view of the possibility of a generalized streptococcal infection he was given a salicylate mixture and prontosil, together with local treatment for the throat.

This was followed by another period of apyrexia for 13 days with diminution of the spleen; the glands in the neck also subsided considerably.

On the 24th August began the third attack of pyrexia and splenic enlargement. This time definite enlargement of the glands of the neck, especially of the left side, with a few in the axillæ and groins was noticed. Considering the possibility of the condition being Hodgkin's disease of the Pel-Ebstein type, we gave him liquor arsenicalis (2 minims gradually increased to 6 minims) twice a day. As the general condition was low and deep x-ray therapy is not so satisfactory in this type of the disease, this treatment was not given. This attack of fever lasted for 15 days.

He was again afebrile for eight days. The size of the spleen and the glands diminished considerably. Next he had low intermittent fever for 12 days. About this time the boy appeared to show some signs of arsenical intolerance; he was disinclined for food, vomited after his breakfast for three days, and complained of pain in the right leg along the sciatic nerve. Arsenic was stopped and some sodium thiosulphate was given intravenously.

On the 28th September the fourth attack of fever in this hospital started. The spleen, as usual, increased and the glands again enlarged. There was definite evidence of neuritis in the right leg, the pain being intense at times; it was most marked in the sole of the foot and behind the leg. The calf was very tender. The knee-jerk was sluggish. There was no anæsthesia. The present attack lasted for a fortnight when the temperature suddenly dropped to normal. Treatment given during this period was mostly symptomatic and consisted of iodides, analgesics and digitalis. The leg was wrapped in cotton-wool and the foot supported between sandbags.

During the next ten days he had a low irregular temperature. The spleen was again reduced and the glands subsided. The general condition was poor. He became very anæmic. On 16th October he was put on a course of campolon injections—4 c.cm. intramuscularly for five consecutive days. On 21st October he was put on ferrous sulphate, 12 grains daily for 21 days. There was some improvement in the anæmia, but with the next bout of fever coming on the anæmia again became severe.

The temperature gradually went up higher daily; this rise constituted the fifth relapse while in this hospital. His condition was now serious and there was high continuous temperature for several days. The stools and urine were passed in the linen and the abdomen was distended and slightly tender. The spleen was enlarged but the glandular enlargement was not very marked this time. During this period treatment consisted of iron, as stated above, stimulants and nursing. The temperature came down about the twentieth day of this bout and it was normal throughout one day but rose again and assumed an intermittent and then a remittent type. The spleen was reduced to $1\frac{1}{2}$ inches and the glands were just palpable.

On 17th and 20th he was given mercurochrome intravenously, 1 c.cm. and 2 c.cm. of a 1 per cent solution.

Physical examination on the 22nd November.—Very low condition: he had a pale yellow complexion and was very anæmic. He had some shivering. The cervical glands were palpable, small, discrete and not painful. Heart slightly enlarged; a systolic bruit was present. Pulse—140 per minute, soft. Respiration—30. Lungs—a few rhonchi behind.

The abdomen was slightly distended, doughy to the feel, with no fluid, but slightly tender.

Spleen— $1\frac{1}{2}$ inches; liver— $\frac{1}{2}$ inch; his face was puffy and eyelids swollen. Both legs and hands were oedematous. He complained of pain in the right leg, especially of the sole, this was less severe than before. Sensation was markedly diminished, almost lost, in the right foot. Motor power of the right leg was practically lost. Knee-jerks were absent. Plantar reflex was normal in the left and lost in the right foot. Sphincter control was impaired. A few small glands were palpable in the groin. He was quite conscious.

After this the boy went steadily down hill; he lost control of his sphincters, but passed very little urine;

his whole body became puffy. On the 25th evening, the temperature fell; he became very collapsed and scarcely recovered consciousness until his death on the 29th.

A distressing symptom that appeared during the last few weeks of the illness was severe pains all over the body, so the patient dreaded being moved or even touched. This made us disinclined to submit him to any treatment that was not aimed at relieving symptoms.

and its replacement by a vascular tissue consisting of lymphoid cells, fair number of both mononuclear and multinucleate giant cells (so-called Dorothy Reed cells), and fibroblasts (plate III, figures 2 and 3). There are also many swollen reticular cells. Many areas of necrosis and hemorrhage may be found scattered irregularly (plate III, figure 4). Eosinophilic cells which are sometimes found in large number in these glands are not seen here.

CHART

Temperature chart showing the characteristic Pel-Ebstein type of fever

The question of deep x-ray therapy was frequently considered but not given for this reason, and in view of the poor results that follow in this type of case.

Further blood examination was made difficult by the general anasarca, and, though we were anxious to confirm the diagnosis by removing a gland and sectioning it, we hesitated to subject the boy to this amount of disturbance.

Other than the cytological examinations of the blood, which we report in detail below, numerous laboratory investigations were carried out during the boy's stay in hospital; these included the Wassermann test, protozoal and bacterial blood cultures, agglutination test on three occasions against the typhoid group, melitensis and abortus, and numerous stool examinations; all gave negative results. An x-ray examination of the chest showed increased hilar shadows; the Mantoux test was negative at 1 in 10,000, but higher doses were not tested; a sputum inoculation into a guinea-pig gave a negative result.

A full post-mortem examination was not allowed but a gland was removed at the time of his death and was sectioned.

The report of Professor M. N. De on this gland was as follows:—

'The lymph node is somewhat enlarged and fairly firm. The cut surface appears greyish-white and congested. Histological examination reveals a complete disappearance of the normal structure (plate III, figure 1)

Blood findings.—The blood count at different periods is shown in the table. At first there was nothing very characteristic about the blood counts. There was marked and increasing anaemia (intermediate haemoglobin estimations are not recorded in the table) of a more-or-less normocytic type. During the fourth febrile bout a most marked large mononuclear increase was observed. Differential counts were done almost daily between 26th October and 9th November; the large mononuclear count varied from 25 per cent on 27th October, when the temperature curve was rising, to 57 per cent on 3rd and 5th November when it was at its peak.

The large mononuclears were unusual in appearance. Treated by supravital staining methods, most of these cells seemed to be of the histiocyte type. Stained by Leishman's, Giemsa's or Wright's methods they appeared large and vacuolated, the vacuoles often overlapping the nucleus and giving it a moth-eaten appearance. In those blood smears made from oxalated blood (potassium oxalate 0.01 grammé

to 5 c.cm. of blood) the vacuoles appeared to be occupied by paired bodies which had the appearance of diplo-bacilli that had not taken the stain; they were shown up best against a coloured background of the cell nucleus, but they were well seen in the cytoplasm in darkly-stained films.

By prolonged staining with Giemsa's stain, they were slightly coloured and a few were seen free, obviously having escaped from cells ruptured during the process of making a smear. They were all the same size—about 2 to 3 μ by 1 μ —and, though most abundant in the large mononuclears, were also present in the polymorphonuclear leucocytes, but not in the lymphocytes or other cells.

These paired bodies interested the writers considerably at the time they were first noticed as this was the first case in which they had been seen. The first impression created was that they were some form of crystalline body, but later we considered the possibility that they were intracellular micro-organisms. With this possibility in view, with the assistance of the bacteriological department of the school, we attempted to grow the hypothetical organism from the blood by a number of methods, including culture on liquid and solid medium, of various compositions, in the presence of oxygen, in the presence of CO₂, and anaerobically, but with consistently negative results. Later, we noticed that the paired bodies were only found in the oxalated specimens of blood and not in the direct smears made at the same time, though the vacuolation in the large mononuclears was still very marked. The bodies were not present in every oxalated specimen and varied in number from day to day (plate III, figures 5, 6 and 7).

This seemed to confirm the first impression regarding the crystalline nature of these bodies. It is interesting that we have not found them before in smears made from oxalated blood, and only on two occasions since; in the blood of an Indian with 'splenomegaly' and in the blood of an Anglo-Indian woman with pernicious anæmia.

Discussion.—On the whole, there seems to be little doubt now that these bodies are crystalline in nature and are produced by the action of the potassium oxalate on some substance in the leucocytes, particularly in the vacuoles which were also seen in the non-oxalated specimens. The reaction has been observed in three cases in which there are few common clinical characters, though they were certainly all cases of anæmia. This further suggests that the change in the chemistry of the white cells, whatever it is, is not specific. The possibility of the bodies being living organisms is not entirely negatived, as one could hypothesize an organism being acted upon and made visible by treatment with potassium oxalate.

It is probable that other workers have observed these bodies in the leucocytes in oxalated blood, but so far we have not seen any reference to such a finding in the literature.

Further investigations to determine the nature of these bodies are under consideration.

Diagnosis.—The clinical diagnosis of Hodgkin's disease was made mainly by a process of elimination, but its accuracy was frequently doubted by ourselves and questioned by others.

The temperature chart had the appearance of the classical Pel-Ebstein type of the disease, but the glandular enlargement was not marked

A RECORD OF RHINOSPORIDIAL POLYPI WITH SOME OBSERVATIONS ON THE MODE OF INFECTION

By G. S. MANDLIK, M.B., B.S., F.R.F.P.S.

Honorary Surgeon for the Diseases of the Ear, Nose and Throat, Sassoon Hospitals, Poona

AFTER the recent publication of 60 cases of rhinosporidiosis by Allen and Dave (1936), this review of my 48 cases collected during the past five years would be of little interest, had it not been for the fact that (1) my cases have been collected from areas of infection which fall in four distinct groups and (2) that a common causal factor of infection is in evidence in all of them.

Ashworth (1923) has concluded that the mode of infection remained undetermined. Allen and Dave (1936) have not been able to discover a common causal source of infection in their 60 cases.

I have tried here to establish, by review and illustrations of case records, that the infection as seen in Poona is 'water-borne'. The cases reviewed are from two districts, Poona and Satara. Two areas of infection have been investigated and the source of infection in the other two is made evident from the review of case records detailed herein.

The first out of the series of my cases in which the rhinosporidium was identified was a polypus removed on 6th February, 1931, from case 1, G. T., a sand-worker.

Group I, Poona.—Source of infection: portion of the river Mula-Mutha between the Holkar bridge and the Jamsetji Bund.

(Continued from previous page)

and was evanescent; on some days even the glands in the neck were scarcely noticeably enlarged.

Another clinical feature was the behaviour of the spleen. In the interval between febrile attacks it was usually just palpable; it began to enlarge just before the temperature rose and continued to do so with the utmost precision by half to three-quarters of an inch a day; with the fall of the temperature it again subsided.

The blood picture gave no assistance; the very marked large mononuclear increase is not a common feature of this disease, nor is the low eosinophil count. The diagnosis was, however, confirmed by the histological section of the gland removed at the time of death; in this the picture was typical of the condition.

Our thanks are due to Captain C. L. Pasricha for his advice and the assistance of his department in the bacteriological examinations, and to Professor M. N. De for his report in the sections of the gland and for the four excellent photomicrographs of these sections, over which he took considerable trouble personally.

An occupational disease

During the succeeding two years, i.e., up to February 1933, eight more rhinosporidial tumours were collected. All the men were 'sand-workers' engaged in collecting sand from the river bed. A common causal factor was at once evident. On 26th August, 1932, case 8, A. K., a carpenter, was seen with a rhinosporidial tumour. He was discovered to have been a sand-worker previously. At this time the mode of infection was not unnaturally thought to be in the peculiar type of work in which these men were engaged, that is, that of collecting sand from the river bed. The disease appeared to be an occupational one.

The portion of the river Mula-Mutha used for the collection of sand lies to the north of the city, between Jamsetji Bund two miles from the Sungum, and the village of Dapodi about the same distance from Kirkee. The men work in groups of 4 to 20 in one area, known as a 'plot', for 2 to 8 hours a day, eight months in the year. About 200 men are engaged in the occupation, but not more than a hundred are engaged in one season, the bigger groups being situated between the Bund and the Holkar bridge, a mile and a half from the Sungum up the river.

In order to ascertain the extent of infection amongst the sand-workers commencing on 10th March, 1933, 55 men were examined.

	All cases	Infected
Number examined	55	10
Ages, years	20 to 40	..
Period engaged, years	1 to 14	2 to 7 (except 1)
Hours of work	2 to 6	..
Nature of work—		
Carters	10	..
Divers	45	10
Habits—		
Smokers	23	2
Non-smokers	16	7
Not noted	16	1

In 14 cases other nasal diseases were present and 10 had chronic catarrh; none of the latter group had rhinosporidial infection.

The men were mostly Bhois or Mahrattas, but there were four Kolis (fishermen) who, though engaged in the work all their lives, were not infected.

None of the members of the families of the workers was infected.

Infection rate in the sand-workers is about 1:5.

By the end of the year 1933, 16 tumours had been collected. Case 15, D. I., a farmer, was noticed to have been infected on the work during the first season's diving. Tumours from case 10, C. N. M., a mason, and case 16, S. I., a *mali*, at Yeravada could not however be traced to this occupation, although there was a probability of the infection coming from the same

source, owing to the use these men made of the area for the purpose of bathing and swimming.

Case 10.—C. N. M., aged 40, a mason, had a rhinosporidial tumour growing from the left olfactory sulcus which was removed on 10th March, 1933. He had never been a sand-worker, but he bathed and often swam in the river between the Bund and the Sungum. The tumour recurred and was removed again on 18th May, 1934.

Case 16.—S. I., aged 30, a mali, rhinosporidial tumour growing from the floor and the left inferior turbinate removed on 6th December, 1933. He was a resident of Belapur and worked as a gardener in a bungalow on the Bund garden road. He was never in the sand-working business, but swam behind his master's bungalow.

Group II, Manchar.—Source of infection: tank to the west of the town.

A polypus removed on 8th January, 1934, from case 17, C. B., aged 25, a merchant, from Manchar was the first indication of the existence of the disease in the neighbourhood of Poona.

He also offered the useful information that some more residents of Manchar were similarly affected, and that all of them, including himself, frequently used an old tank in the town for swimming and bathing.

Manchar is situated on the right bank of the Ghodnadi river, about 12 miles north of Khed and 37 miles north of Poona. It is a market town with a population of about 4,000. To the west of the town, beyond a watercourse, is a reservoir about 25 yards square with two flights of steps leading to the water. The west wall has a niche (3 × 2 × 6 feet) with carved side posts and sculptured foliage. Within the niche is a much-worn Devnagari inscription difficult to read. A separate well nearby is reserved for obtaining drinking water.

A brook running north to south, which is nearby, is also used for swimming, when full, in the rainy season.

On 26th January, 1934, at this source of infection I collected three specimens and examined 32 bathers in the tank. The tumours removed were from cases 19, 20 and 21. In all, five cases of rhinosporidial infection were observed, one being an eye infection.

All persons examined were students. The duration of infection was between 1 to 2 years.

Infection amongst the bathers was 1 : 8. All were males.

My thanks are due to Dr. M. G. Bhave, medical officer in charge of the charitable dispensary at Manchar, for permitting me to operate at the dispensary and for the help in conducting the investigation.

Case 28.—H. K., aged 23, a merchant, had the rhinosporidial tumour removed on 25th January, 1935. Tumour growing from the floor of the left nostril. Duration of symptoms, one year. Nine months before he had stayed at Manchar for four months. During his stay there he used frequently to swim in the tank.

Case 38.—S. G. K., aged 26, a hawker in bangles. Operation on 7th August, 1935, for a rhinosporidial tumour on the floor of the right nostril. He had stayed at Manchar two years ago for three months and used to swim in the tank then. Symptoms of epistaxis for the past six months only. A very vascular tumour had been removed previously elsewhere.

A water-borne disease

It had now become evident that the disease as it appeared in Poona was no longer limited to the sand-workers. Could there not be some factor common to both Poona and the Manchar cases? The sand and the fish as a source of infection, not found in the tank at Manchar, were ruled out. The silt and the mud perhaps, but the water, the stagnant water, certainly was essentially the same in these two places.

The water in the tank at Manchar was stagnant throughout the year, excepting an occasional overflow in the rainy season. The water in the Mutha river beyond the Sungum was dammed across by the Jamsetji Bund about 2 miles down the river. In spite of the sluices in the Bund, silt and sand accumulated in the bed of the river. There was water stagnation to a great extent.

Some cases illustrating the water-borne nature of the infection in the Poona group, in persons other than the sand-workers:—

Case 33.—D. N., aged 20, a peon, tumour removed from the right side of the septum on 15th May, 1935; used to swim in the river behind the Maharaja of Kolhapur's bungalow.

Case 39.—G. B., aged 17, a potter, bathes in the river above the Sungum and collects mud and earth from the river bed for making bricks. Rhinosporidial tumour removed on 25th September, 1935, from the left side of the septum.

Case 40.—B. J., aged 25, a Bhoi, fisherman. Tumour removed from the spur on the right side of the septum on 1st November, 1935. Once removed three years ago. Bathes and swims near Sungum.

Group III, Satara.—Source of infection: three tanks in the city, Mangalwar, Machi and the municipal tank.

The suspicion aroused regarding the water-borne nature of the infection was brought a step nearer conviction by the appearance of this group of cases. The first to come under notice was case 22, S. R. K., a student, seen on 20th April, 1934, with a rhinosporidial polypus arising from the floor of the left nostril. Case 24, S. D. G., a teacher from Yawatmal in the Central Provinces, followed on 11th May, 1934. The infection was traced to the source at Satara, which place he often visited during holidays. Case 26, B. J., a clerk, had his polypus removed on 17th October, 1934. Suffered from attacks of epistaxis for three years. He gave a history of exposure to infection at Satara seven years previous to the appearance of the symptoms. Case 22 brought his brother, case 27, D. R. K., also infected at Satara, for operation on 23rd November, 1934, thus completing my first five cases from this group. They were all used to bathing and swimming in one or more of the three infected tanks in that city.

Case 25.—N. N., aged 19, rhinosporidial polypus growing from the junction of the septum and olfactory sulcus left side. Operation on 15th June, 1934. Till last year bathed in Phutka tank, now bathes in the municipal tank, Satara.

Case 26.—B. J., aged 25, a clerk. Growth in the right nostril growing from the olfactory sulcus. Presence of the growth noticed for one month. Exposed to infection one year ago. Previously once operated on for epistaxis, three years previously a vascular growth had been removed. He had been exposed to infection seven years before. Now resident of Poona.

Satara is 69 miles by road to the south of Poona, situated on a slope below a range of hills which form a semicircular girdle round a

Case 45.—B. S., aged 22, a goldsmith, rhinosporidial growth in nose removed on 12th June, 1936. He visits Oundh every two or three months, and swims in the tank whenever he visits Oundh. He also visits Satara and used the Mangalwar tank a year ago once. He is a resident of Poona but never bathes in the Sungum area.

Summary of the case records

Forty-eight cases examined and treated from 6th February, 1931, to 25th October, 1936.

TABLE

Number of the group	I	II	III	IV	TOTAL
Name of the group	Poona	Manchar	Satara	Oundh and Yelliv.	..
Place of infection	River Mula-Mutha, near Sungum.	Tank west of the city.	Three tanks	Old wells	..

Occupation—								
Sand-workers	18	18
Students	5	6	1	12
Others	6	3	5	2	16
Not known	1	..	1	..	2

REMARKS.—The duration of the disease was up to seven years. The symptoms appeared from within a year to several years after exposure to infection. All persons infected were males.

recess, with the fort on the south and the Yawateshwar hills on the west. All drainage goes to the Yenna on the north by means of brooks rising from the hills on three sides. The city has several wells and tanks. Many of the tanks have now dried up. The three tanks to which the infection is traceable are constantly in use for the purpose of bathing and swimming, particularly in the hot weather.

The largest and the oldest is the Mangalwar or Shripat tank to the west of the city. The Phutka talao is in Machi peth near the foot of the hills and the municipal tank in Bhavani peth, though smaller, is very popular. The students in particular use this, because it is near the school and more central. The extent of infection in the swimming population was not investigated, but from the survey of cases the source of infection can be quite definitely traced to these tanks.

Group IV, Oundh and Yelliv.—Source of infection: old wells in the respective places.

In order to complete the record, three cases are included in this group provisionally, case 13 seen on 30th June, 1933, from Khamgaon in Bhimthadi subdivision. The village has not been traced and is included in this group for convenience.

Case 44.—K. A. G., aged 16, a student, rhinosporidial growth removed on 18th March, 1936, from right inferior turbinate. History of swimming in old well in the village of Yelliv and a tank at Oundh. He knows of some more persons with such growths using the well and the tank.

Outstanding signs, symptoms and treatment

Epistaxis, the presence of a strawberry red growth, and nasal obstruction are the three outstanding symptoms. When the tumour is deep in the nose, epistaxis is the first symptom. Obstruction is usually the last. The sand-workers complain of inability to remain under water long enough, even with very small growths. Unlike ordinary nasal polypi these growths never cause a 'frog-nose'. Sessile growths have often a linear attachment of a mucous fold from which they grow into the cavity of the nose. Treatment is surgical. The knife is used after localizing the attachment. Allen has tried neostibosan with variable results. A rapid diagnosis is arrived at by dropping the polypus in Zenker's fluid; hundreds of tiny leaflets stand out from the surface of the polypus in a few minutes, the red colour changing to ash-grey.

Conclusions

In the cases so far recorded from elsewhere no common cause of infection has been noted. From the review of cases recorded here it is clear:—

(i) that the rhinosporidial infection in Poona and the neighbourhood is localized to areas divisible into groups,

(ii) that the infection in these groups is localized to infected water of the wells, tanks, or an infected section in the course of a river,

S. W. = Sand-worker. Rec. = Recurrence.

(iii) that the infection is transmitted in the process of bathing, swimming or diving, and (iv) that the part played by the fish or other aquatic hosts, if any, is not certain, but the sand and the silt probably help the process of transmission.

Ashworth (1923) refers to direct transmission of discharged spores as an obvious method by which the infection could be spread from man to man. It is here suggested that the spread takes place through the medium of water, possibly stagnant water.

Spores in the trophic stage with a stout chitinous envelope have been known to exist in the epidermal layer, probably having thrust their way through from the subjacent connective tissue. It is possible to imagine that such spores floating in the infected water similarly find their way into the epidermal layer from without.

The fact that the carters engaged on the sand work are not infected suggests that mere bathing in infected water is not enough. Swimming, which ensures frequent and more prolonged contact with the spores, and diving, which presses the spores against the nasal mucosa by virtue of the force of the dive and the increased water pressure, are necessary for a successful graft or anchoring of the spores. It may even be possible that this force drives the spores through the mucosa from without in the same way as the increased lymph pressure in the connective tissue has been suggested to thrust them from within. The spores are non-motile, and some such external force would seem necessary.

Whether the spores in infected water remain in the trophic stage or whether a flagellate stage exists is not known, nor is it yet certain whether the sporangium is parasitic in any of the aquatic species.

The occurrence of infection in persons exposed to infection varies within a wide range. A few contract the infection within the first year, but the majority appear to resist infection over a period of some years.

Catarrhal and suppurative conditions of the nasal cavity would seem (from group I) to resist infection, possibly on account of the phagocytic action of the inflammatory cells present in the tissues under the mucosa, in such affections of the nose.

R. E. Wright in 1922 suggested the possibility of the transmission of the organism through water, but his cases did not reveal any such common cause. In the cases recorded and grouped as above, a common cause for such a mode of transmission is made evident for the first time.

All the examples of rhinosporidium from man studied so far appear to be referable to one species, the systematic position of which, according to Prof. Ashworth, is referable to the

THE BISULPHITE-BINDING POWER OF THE BLOOD IN CASES OF EPIDEMIC DROPSY, ANÆMIA AND MALARIA AND ITS POSSIBLE BEARING ON A VITAMIN-B DEFICIENCY

By H. ELLIS C. WILSON, M.B., CH.B., D.SC.

Professor of Biochemistry and Nutrition

and

B. K. GHOSH, M.Sc.

Department of Biochemistry and Nutrition, The All-India Institute of Hygiene and Public Health, Calcutta

PETERS and SINCLAIR (1933) have shown that in pigeons suffering from vitamin-B₁ deficiency the brain, when incubated with lactic acid, produced pyruvic acid in appreciable amount whereas when the brain of normal control birds is substituted this is not produced. Peters and Thompson (1934) further showed that pyruvic acid is probably a normal intermediary in the course of carbohydrate metabolism. In vitamin-B₁ deficiency the metabolism of carbohydrate appears to be held up at the pyruvic acid stage; this leads to an accumulation of this substance. The exact precursor of pyruvic acid and its normal fate, oxidation or re-synthesis, is at present obscure. The fact however of its appearance in the tissue in this condition is all that need concern us in this preliminary report.

This discovery led to an estimation of pyruvic acid in the blood of pigeons suffering from vitamin-B₁ deficiency. Thompson and Johnson (1935) found the blood pyruvate to be increased from a normal value of 3.46 mg. to 11.31 mg. per cent in affected animals. The method they employed, namely, the bisulphite-binding power (henceforth B.B.P.) is not however specific for pyruvic acid, but Johnson (1936) later isolated pyruvic acid as the 2.4 dinitrophenylhydrazone. Platt and Lu (1936)

(Continued from previous column)

fungus group of the Phycomycetes, suborder Chytridineæ, and provisionally near the Olpidiaceæ.

It is as yet undetermined whether the organism found in Poona and the neighbourhood, with such strong affinity for water, may not belong to an allied but a separate sub-group of its own.

Compiled from my notes on the cases seen and treated at the Sassoon Hospitals, Poona, and published with the permission of and thanks to the Civil Surgeon, Lieut.-Col. R. H. Candy, I.M.S., Poona.

in China investigated the B.B.P. of the blood of patients suffering from beri-beri and other conditions and showed that the B.B.P. was increased from a normal figure of 3 to 4 mg. to about 11 mg. per cent in cases showing clinically

bicarbonate, and estimating the released bisulphite by titration with a standard iodine solution.

The data obtained from the five groups of patients and one normal group are given below:

TABLE

GROUP A Normal	GROUP B Malaria without anæmia	GROUP C Anæmia	GROUP D Epidemic dropsy	GROUP E Diabetes	GROUP F Spleno- megaly
3.23	3.39	5.80	8.90	6.2	5.2
3.25	3.51	6.60	8.40	6.3	5.35
3.70	3.70	5.70	8.30	6.9	5.3
2.9	3.60	6.85	8.30
3.55	3.8	5.90	8.42
3.66	..	5.10	7.69
Average 3.38	Average 3.58	Average 5.99	Average 8.33	Average 6.47	Average 5.28

varying degrees of beri-beri. They found, however, that not all the B.B.P. in every cases was due to pyruvic acid, in contrast to the finding in pigeons with experimental vitamin-B deficiency. They suggested that similar observations might be carried out in cases of epidemic dropsy (often called beri-beri in Bengal) which has at times been thought to be associated with a vitamin-B deficiency.

Dr. L. E. Napier, who had seen some of Platt and Lu's work when he visited the Lester Institute at the time of the Far Eastern Association of Tropical Medicine meeting of 1934, drew the writer's attention to Platt and Lu's paper and suggested that, as well as in cases of epidemic dropsy, the test might be carried out on a number of his cases of anæmia and in normal persons of the same class, as it had been shown that vitamin-B deficiency was the cause of a type of macrocytic anæmia that occurred in Bombay (Wills, 1931), and he himself had found that a diet rich in vitamin-B complex effected a cure in certain cases of anæmia in Bengal (Napier, 1936). The majority of the bloods tested in this investigation were from patients of the hospital attached to the Calcutta School of Tropical Medicine, and the necessary clinical data were supplied by him. The cases investigated included epidemic dropsy, anæmia, malaria (without anæmia), splenomegaly, and diabetes. In addition blood from five healthy well-to-do Indians and one European was investigated in order to compare the normal standard B.B.P. of the blood with that obtained by Platt and Lu.

The B.B.P. in the blood was determined by the method of Clift and Cook (1932), so that the results might be comparable with those of Platt and Lu who used the same technique. The essentials of the method consist of forming the bisulphite compound of pyruvic acid, aldehydes or ketones, hydrolyzing it with sodium

It will be noted that the highest average B.B.P. is found in cases of epidemic dropsy. The figure is also considerably increased in cases of anæmia, splenomegaly, and diabetes. The differences between malaria (without anæmia) and the normal are the only ones which are not statistically significant by Fisher's 't' test. We do not, however, lay too much stress on all the results, bearing in mind the fact that the method is not specific for pyruvic acid. In the diabetics, for instance, it is possibly due to traces of acetone in the blood. The fact that most groups of patients show an increased B.B.P. of the blood may be due not so much to the disease itself as possibly to the fact that the hospital class are all suffering from a variable degree of vitamin-B₁ deficiency. It would appear, however, that in the cases of epidemic dropsy and anæmia there is an unmistakable increase in the B.B.P. of the blood. This may be due to the presence of some substance or substances, pyruvates, methylglyoxal or aldehydes, which are increased in the blood in these conditions. Previous work in this laboratory has shown that the blood uric acid in epidemic dropsy, as estimated by the arseno-phosphotungstic acid reagent of Benedict and Franke (1922), is increased. We tested a solution of pyruvic acid which probably contained allied substances usually found in association with pyruvic acid, and observed that it gave a slight colour with the uric acid reagent. It would then tend to confirm the observation that there is some substance or substances present in abnormal amount in the blood in epidemic dropsy. This substance combines with bisulphite and possibly reacts to a certain degree with the arseno-phosphotungstic reagent.

Further work will have to be done in order to find out whether it is due primarily to pyruvic acid, methylglyoxal or some other substance. Whether our findings indicate a deficiency of vitamin B₁ or an allied vitamin cannot

be stated at present. It should be pointed out again that Platt and Lu found that in many cases the total B.B.P. of the blood of beri-beri patients could not be accounted for entirely as pyruvic acid, in contrast to the findings in experimental beri-beri. It is possible that epidemic dropsy and some of the anæmias may be associated with partial deficiency of this vitamin or its imperfect absorption and/or utilization in the tissues. It is proposed to take up the question of the vitamin-B₁ excretion and saturation of patients in order to obtain more information on this point.

In regard to the anæmias it is premature to make definite statements. The increase in the B.B.P. of the blood, although much less than in the cases of epidemic dropsy, was nevertheless nearly double the normal value. In view of the fact, however, that some of the anæmias in this country can be cured by a good diet (Napier, 1937) or by protective foods, such as marmite (Wills, 1931), which is rich in all the vitamins of B group, the findings recorded here are of interest. At the present time some six different factors have been obtained from yeast; some are necessary for man, others for rats or birds. It is possible that all—in varying proportion for the different species—are necessary for normal health. The incidence and clinical expression of a deficiency may vary according to the relative proportion of the different factors of the B group in the dietaries concerned. This conception is not new, in view of the fact that there is a certain amount of evidence for the existence of more than one form of vitamins A and D.

Conclusions

1. The bisulphite-binding power is increased in the blood of cases of epidemic dropsy, anæmia, splenomegaly and diabetes.

2. The significance of those findings in relation to a vitamin-B₁ deficiency is discussed.

3. The possibility that different deficiency diseases may be due to the relative lack of one of the several components of the vitamin-B complex is discussed.

We desire to acknowledge the help of Mr. Swarup for checking the statistical data.

Protocol on the statistical treatment of the figures

In order to find out if the differences in the five groups are significant when compared to the normal, group A, Fisher's 't' test has been applied, viz:—

$$t = \frac{(\bar{x}_n - \bar{x}_i)}{s \sqrt{\frac{1}{N_n} + \frac{1}{N_i}}}$$

(Continued at foot of next column)

THE EGGS OF *TÆNIA SOLIUM* AND *TÆNIA SAGINATA*

By P. A. MAPLESTONE, D.S.O., D.Sc., M.B., B.S., D.T.M.
(From the Helminthological Research Laboratory,
School of Tropical Medicine, Calcutta)

IN a recent search of the literature for records of *T. solium* in India several papers were found in which infection with this parasite was distinguished from that of *T. saginata* by stool examination when only eggs were seen.

The generally accepted teaching is that *T. solium* eggs are globular and *T. saginata*

(Continued from previous column)

where \bar{x}_n denotes the mean of the normal group.

\bar{x}_i denotes the mean of any other group
(i varying over groups).

s is the pooled estimate of the variance obtained from the following formula:—

$$s^2 = \frac{S_n (\bar{x}_n - \bar{x}_n)^2 + S_i (\bar{x}_i - \bar{x}_i)^2}{(N_n - 1) + (N_i - 1)}$$

where N_n denotes number of observations in the normal group.

N_i denotes number of observations in the other group.

The value of 't' taken in conjunction with the degrees of freedom (two less the number of observations of both groups) will show from statistical tables whether the difference is significant in each case.

Groups	't'	Degrees of freedom	
A and B	1.2903	9	Not significant.
A and C	9.0218	10	Significant.
A and D	24.324	10	"
A and E	13.205	7	"
A and F	10.1442	7	"

* All measurements in microns.

With the exception of Mönnig in the above list of authors it can be reasonably inferred that the measurements of the eggs of these two species of tapeworm have been copied from book to book without any attempt to confirm the particulars given. In the literature available it is not possible to find who first published the statements but at least they date from 1908, the fourth edition of Braun's 'Die Tierschen Parasiten des Menschen', for it is from this that much of 'The Animal Parasites of Man' by Stephens, Fantham and Theobald was translated.

Two other books, Southwell (1930) and Blacklock and Southwell (1935), have not been included in the above list because they make the revolutionary statement that the eggs of these two parasites are indistinguishable. When it is noted that the first of these two books appeared in 1930 and that five of the books cited above were published three or more years later it seems that Southwell's statement has been missed by the authors concerned or it is disbelieved and has therefore been ignored. As far as the writer is aware Southwell has never published any detailed observations to prove his remark so it is possible this is why it has not been referred to in other works. It is with the object of emphasizing and drawing attention to what is an important correction in a practically universally held belief that the following small research has been carried out.

and a number of the eggs placed on slides in water. One hundred eggs, taken as they appeared in the microscopic field and without selection, were measured in two diameters, the longest and shortest. Both worms had been in formalin for a year or two, but this is of no importance as tapeworm eggs remain unaltered indefinitely, in properly preserved material. The eggs were measured under a one-sixth objective combined with an eyepiece micrometer that gave a total magnification of approximately 300 diameters. Each division of the micrometer was 3.9μ , and in measuring the eggs differences of approximately 1μ were recorded by estimating, when both edges of an egg did not coincide with two of the scale divisions, whether it extended for $\frac{1}{4}$, $\frac{1}{2}$ or $\frac{3}{4}$ of a division. In giving the results it was found advisable to combine the measurements in groups representing one division of the micrometer scale, that is about 4μ , as this smoothed out any apparent discrepancies that showed when individual variations of 1μ were taken, on account of the relatively small number in each group in the latter case. All the maximum and minimum diameters of the hundred eggs for each species are taken together and appear in the table as the numbers in one hundred measurements.

In addition to these hundred eggs for each species one abnormally large egg measuring $50 \times 43 \mu$ was noted in the *T. saginata*, and in the *T. solium* slide one egg was seen with a

TABLE

Size of diameter	MAXIMUM		MINIMUM	
	<i>T. solium</i>	<i>T. saginata</i>	<i>T. solium</i>	<i>T. saginata</i>
31-34 μ	4	5	57	58
35-38 μ	28	39	43	42
39-43 μ	66	54	0	0
Over 43 μ	2	2	0	0

minimum diameter of 30 μ ; this was the smallest egg seen. The latter observation is of interest when it is remembered that the shorter diameter of *T. saginata* is practically universally recorded as 20 to 30 μ , well below the shortest diameter noted in this investigation with one exception.

If the grouping is slightly altered from that given in the table and the eggs with minimum diameters of 32 to 35 μ are taken together it is found that 81 *T. solium* and 86 *T. saginata* eggs fall within it. During this examination three *T. solium* and six *T. saginata* eggs were measured which showed diameters equal in both directions, that is they were apparently globular. In the case of *T. saginata* the six eggs were all between 33 and 35 μ in diameter, two of the *T. solium* eggs were 35 μ and the other was 32 μ . That is, these eight eggs are all in the group containing over 80 per cent of the recorded minimum diameters, so it is suggested that eggs with equal diameters in both directions are possibly oval eggs that are being viewed end on, and that consequently only the minimum diameter is visible. It is a common experience in examining hookworm eggs in large numbers, as in the course of counting, to see an occasional egg that is lying in this position and therefore has a circular contour, but no one has yet suggested on this account that some hookworm eggs are globular.

The coincidence in the measurements of the eggs from these two worms is so remarkable that it was not considered worth while measuring more than one hundred of each to establish the fact that, for practical purposes, they are indistinguishable.

Conclusion

The statement by Southwell (1930) that the eggs of *T. solium* and *T. saginata* are indistinguishable has been shown to be correct, and a study of the literature has revealed an excellent example of the all too common habit that authors have of taking a statement from older publications and copying it year after year without it being put to the proof of correctness.

THE GIANT-CELL TUMOUR OF BONE

(WITH A REPORT OF SIX CASES)

By V. S. HARIHARAN, M.B., F.R.C.S. (Eng.)
 Surgeon, Ramakrishna Mission Hospital, Rangoon

AMONGST all the controversies regarding the classification of osteogenic neoplasms, the giant-cell tumour, under one name or another, has always remained a distinct entity. In fact, the subject of contention in this connection has been the nomenclature of this distinct variety of tumour formation in the bone which, though locally destructive, practically never presents any of the general features of malignancy. It has been very widely known as the myeloma of bone, but to differentiate its origin from the osteopoietic tissue of the bone as distinct from the multiple myeloma arising from the hæmopoietic tissue in the bone-marrow this term has been found to be rather unsatisfactory. The appendage of *sarcoma* as in myeloid sarcoma and giant-celled sarcoma is a misnomer and, besides leading to confusion, gives the tumour a serious prognostic outlook which is far from being correct. Osteoclastoma—the name recently suggested by M. J. Stewart—begs the question of the origin of the giant cells in the tumour, and, so long as this question as to whether they arise from the osteoclasts or the endothelial cell of the bone remains *sub judice*, this nomenclature is rather unacceptable. The consensus of surgical opinion is that the term giant-cell tumour suggested by the American registry of bone sarcoma is satisfactory though not perfect, and among the other tumours of the bone containing giant cell this remains a distinct entity.

The nomenclature is made more difficult because of the lack of definite knowledge regarding its ætiology which is no exception to the vexed question of the ætiology of tumours in general. It occurs equally well in adult men as well as women and is rarely known to occur in children. It has practically no causative connection to trauma of any nature, though a history of trauma is often obtainable. It is rather accidental than causative.

The giant-cell tumour may be periosteal arising from the periosteum of the upper or the lower jaw where it constitutes one variety of epulis, or it may be medullary in type arising from the endosteum of the extremities of certain of the long bones such as the head of the tibia, lower end of femur, upper end of humerus, lower end of radius, upper end of fibula and occasionally at the sternal end of the clavicle. Rarely it is found to occur at the non-osseous sites such as the tendon sheaths, bursæ and capsule of joints. The endosteal form occurs in the diaphyseal end of one of the long bones mentioned above, where the affected part is expanded to form a tumour of varying size. The tumour is somewhat rounded in shape, the bone appearing

to expand more or less equally in all directions or it may project more in one direction than the other. It is covered by periosteum and the bony shell underneath may be so thinned out that a sensation of egg-shell crackling is obtained on pressure with the finger.

The cut surface usually exhibits a uniformly dark-red appearance owing to its great vascularity and the presence of blood clots. More frequently it looks somewhat mottled like the cut surface of a pomegranate, the lighter areas indicating the sites of old and altered blood clots or of patches of degenerated necrotic tissue. With advancing degeneration, cysts containing a brownish fluid form inside the tumour. Round the periphery of the growth is a narrow zone of more solid tissue, pinkish-white in colour, indicating a zone of more active tumour growth. This has a low local malignancy destroying the shell of overlying bone. New bone is formed from the osteogenic shells of the periosteum to form a new bony wall to the tumour. The bony shell of the tumour is thus re-formed from the periosteum after destruction by the tumour growth, or it is possible that it is the expanded remnant of what was once the wall of the normal compact bone. The remains of the cancellous tissue may be represented by a few odd spicules of bone scattered irregularly in the pulp of the tumour.

The periosteal variety grows from the alveolar margin of the jaw in the form of a hard, more or less pedunculated growth covered by mucous membrane unless it is ulcerated.

Histologically, the tumour is made up of spindle-shaped cells without hyperchromatic nuclei. But what catches the eye most is the presence of large numbers of giant cells of different sizes, numerous in one part of the microscopic field and scanty or absent in another. The giant cells possess numerous small oval nuclei situated towards the centre of the cells and not around the periphery as in tuberculosis. The cytoplasm is opaque, abundant, and basophilic. These have the general characteristics of foreign-body giant cells and may be large osteoclasts or may be derived from the endothelial cells of the bone. No atypical forms are seen as in sarcomas. Numerous wide thin-walled blood vessels are seen with extravasated erythrocytes showing the tumour to be highly vascular. Some areas may reveal the remains of the osseous lamellæ homogeneous in appearance and stained red by eosine, patches of myxomatous and fatty degeneration and areas of necrosis with feebly-stained cells and degenerating nuclei.

Osteitis fibrosa cystica, first described by von Recklinghausen in 1891, seems to have a direct relationship to the giant-cell tumour of the bone. Cases have been described from time to time (like case 6 herein reported) where different portions of the same tumour present the typical appearances of the giant-cell tumour and of the

fibrocystic disease of the localized type. Cysts form in both conditions and typical giant cells, as in the giant-cell tumour, are often found in the walls of the cysts in the localized fibrocystic disease of bone. Typical giant-cell tumour is also known to arise from a previous case of localized fibrocystic disease, as is probably the case in case 3 herein reported. Pathologically many American authorities, notably Ewing (1922), consider the giant-cell tumour as a separate variety derived from a common condition—osteitis fibrosa cystica.

Bloodgood (1910) and others consider the fibrocystic disease to be essentially inflammatory in origin, *i.e.*, a low-grade form of osteomyelitis. Or it may be one of the obscure disorders of calcium metabolism due to hyperactivity of the parathyroid glands. Phemister and Key (1933) suspect a low-grade infection and claim to have cultured the infective organisms from the cyst wall of some of their cases.

The direct relationship between osteitis fibrosa cystica and the giant-cell tumour, as explained above, makes one agree with Barrie who considers the process in the giant-cell tumour to be inflammatory and not neoplastic, and to him it is a chronic hæmorrhagic osteomyelitis. Considerable evidence is also accumulating to show that the bone cysts and possibly the giant-cell tumours are due to the hyperactivity of the parathyroid glands.

The condition is essentially chronic in nature. The patient complains of slight fleeting pain, but never severe as in sarcoma, of a swelling in one of the usual sites of tumour, or he may consult for a fracture of the bone due to some very trivial accident or violent muscular movement. Thus pain, swelling, or spontaneous fracture form the three essential symptoms of the condition.

On examination, a tumour of varying size is discovered in one of the usual sites of the condition, towards the ends of the bones. It is more or less rounded in shape, situated more on the diaphyseal side of the end of the bone, though the epiphysal side may also be involved by the local destructive process. The articular cartilage remains more or less intact and movements of the joint may be obtained but for the mechanical impediment due to the size of the tumour. The adjacent joint may contain slight fluid as a result of synovitis. The tumour may be hard, soft, or fluctuating giving an egg-shell crackling according to the extent of degenerative processes and bony destruction by the subjacent tumour growth. Blue telangiectatic veins may be present coursing over the subcutaneous surface of the tumour, caused by mechanical pressure of the tumour on the main venous channels, and rarely the tumour may be hot and pulsating due to the highly vascular nature of the tumour. More rarely still it may have ulcerated presenting a raw red fungating ulcer on the surface exuding a sanious fluid or

even blood and presenting a hæmorrhagic appearance. The bone distal to the tumour is normal and there may be a fracture at the site of the tumour. The distal portion of the limb is usually normal but may occasionally be œdematous from venous obstruction. The general condition of the patient is good except for any secondary infection from an ulcerated tumour. The urine is normal and does not contain Bence-Jones protein, which is only found in cases of multiple myelomata and in some cases of generalized fibrocystic disease.

X-ray shows the end of the bone expanded with the rest of the diaphysis normal and with no inflammatory periostitis round the tumour. The expanded shell of bone may present varying grades of thickness with the lamellæ of bone traversing the matrix and dividing it up into cysts of different size and number, giving the whole tumour a honeycombed appearance. The lower limit of the tumour appears rounded and cut off distinctly from the rest of the diaphysis. Fracture, if present, is detected by the discontinuity in the length of the bone, and when the bony shell growth is notable, to keep up with the destructive process of tumour growth, the shells of bone appear as islets of thinned out bone with discontinuity of bone surface.

The diagnosis is rather difficult even with the help of x-ray pictures. It has to be differentiated from the other bone conditions of a similar nature, such as the Brodie's abscess, tuberculosis, and gumma of the bone, the many varieties of sarcoma, secondary carcinoma and the occasional hydatid cyst in the bones. Rarely enough it may be mistaken for osteomyelitis. A systematic examination together with x-ray will go a long way to help to arrive at the correct diagnosis of the condition. Difficulty arises in differentiating it from fibrocystic disease because one may develop into the other or both may be associated together in the same condition.

The treatment is essentially conservative in nature. Local excision removes the growth, and in cases where portion of the compact bone can be saved partial excision with thorough curettage of the tumour tissue together with swabbing the residual bony cavity with carbolic and alcohol or iodine will be sufficient to ensure a permanent cure of the condition. Recurrences are rare or uncommon. Where the tumour occurs in single bones of the limb excision will leave the distal portion of the limb unsupported. A successful bone graft has saved many a limb in such cases. However this has to be considered more seriously in the case of the lower extremity where the question of weight-bearing has to be specially considered. When it is highly doubtful whether this will be possible, amputation of the limb will have to be resorted to, but in all cases amputation must be regarded as a last resort. Even in cases of the lower extremity conservative measures with

bone grafting, if necessary, may be given a trial in the first instance and amputation resorted to only if it proves a failure. The recuperative and compensatory processes of nature are well known to be far beyond the ken of human judgment and it is always advisable to give the patient the benefit of the doubt. However perfect an artificial limb may be it is hard to compare it with nature's handiwork, not to speak of the sentiments of the patients. However, in really hopeless cases there is no use stretching the argument to the extreme and submitting the patient to the risks of operation twice. The surgeon's responsibility is thus enhanced in arriving at the correct decision in the matter of amputation.

The following cases tend to throw some light on some of the problems that present themselves to the surgeon when dealing with the varieties of this condition.

Case 1.—Patient A., aged 18, male, was admitted into the hospital in May 1933 with a tumour on the upper end of the left humerus. The duration of the disease was 13 months. He had slight pain, but not so severe as to interfere with his work.

The tumour was large and rounded, of the size of a tennis ball, occupying the whole of the upper end of the humerus including the epiphysal region. The surface veins were evident as blue lines coursing irregularly over the surface. There was slight pulsation on palpation as also egg-shell crackling. The rest of the humerus felt normal, as also the distal portion of the limb. There was slight limitation of movement at the shoulder only due to the size of the tumour.

X-ray showed a typical giant-cell tumour of the upper end of the humerus.

The patient refused operation and absconded. Local excision of the tumour with a bone graft from the tibia as in case 6, below, would have cured the disease and at the same time saved the limb.

Case 2.—Patient B, aged about 36, female, was seen by me in October 1933 on account of a fall she had and consequent injury to her right knee. She had pain in the upper end of the tibia for about a year. She had consulted doctors who after proper examination and x-rays had diagnosed the condition as a giant-cell tumour of the upper end of the right tibia. On examination the region of the knee joint was swollen and the skin discoloured. It was warm on palpation and there was distinct egg-shell crackling on the outer aspect of the upper end of the tibia in front of the head of the fibula. It was very tender and the knee joint was distended with fluid. There was rather free movement at the knee joint limited only by the synovitis and the tenderness due to the injury. There was slight œdema of the leg distal to the knee. X-ray showed a typical giant-cell tumour on the upper end of the right tibia, with the shell of bone intact and with no fracture of the bone.

The knee joint was aspirated and about two ounces of thick blood-red fluid were removed. Lead lotion was applied and the knee joint kept at rest. The inflammation subsided gradually and the joint was kept at rest in a stiff knee cage and the patient not allowed to walk about.

On further consultations the consensus of surgical opinion was that amputation at the lower third of the thigh was the only safe treatment feasible because it was the tibia that was affected and that after any local excision there would not be proper support for the leg to bear any weight. The patient was averse to operation of any sort and was much less willing for amputation.

However I advised a conservative operation in the first instance and that the radical amputation could be

done if this were to prove a failure. After due consideration the patient consented to the operation and the further course of the case showed the wise move she had adopted.

She was operated on in December 1933. The great danger at the time of the operation is hæmorrhage and the later danger is infection. The latter makes the healing process long and tedious and kills the bone graft, if any. All steps were taken to effectively prevent the advent of any secondary infection together with the no-touch-technique throughout the operation. A tourniquet was applied to the middle of the thigh to control the hæmorrhage and in fact at the end of the operation she had lost less than two drams of blood. Pure chloroform was used as the anæsthetic. Since the patient was very nervous there was no question of using local or spinal anæsthesia and since she had a history of pleurisy and tuberculous glands in the neck ether as an anæsthetic was strictly avoided.

An external linear incision four inches long was made stretching downwards from the level of the knee joint. Particular care was taken not to open the joint. The bone was freely exposed and a shell of bone one and a half inches in diameter was punched out from the outer condyle of the tibia in front of the upper tibio-fibular articulation. The whole of the tumour-laden cavity was thus laid open. The tumour mass was thoroughly scooped out until bare bone was felt in the posterior medial and lower aspects. Towards the articular aspect the less hard articular cartilage was felt, and particular care was taken not to damage the integrity and continuity of this. The whole cavity was then swabbed with phenol and then with rectified spirit. A few chips of bone were chiselled out from the middle of the shin of the same tibia and these were packed into the bony cavity left behind. A flap from the peroneal muscles was also separated distally and turned up into the cavity so as to fill in the same. The wound was sutured over in two layers with interrupted stitches and dressed. A back splint made of a plaster-of-paris slab was applied stretching from the middle of the thigh to the sole of the foot so that the knee and ankle joints were both immobilized. The tourniquet was then removed. The patient had an uninterrupted recovery with a maximum temperature of only 99.5°F. for three or four days. The stitches were removed on the tenth day and the whole limb put in plaster-of-paris casing from the middle of the thigh and including the foot.

Since it was rather uncomfortable the plaster casing was slit up two weeks later into two halves, upper and lower, and the limb still kept immobile. Two weeks later passive movements were started for the ankle joint and five days later for the knee joint also. In six weeks the patient was able to sit up in bed and move the joints herself, with the use of the back splint only at nights. In two months the splint was completely removed. The site of the tumour was hard to the touch and the outer condyle of the tibia felt hard and rounded. There was little or no pain. Medical diathermy and ultra-violet-ray exposures were given for about a week. She was allowed gradually to bear weight on the affected leg, first with the help of a stick and later without it.

Pathological examination of the growth removed at the operation showed typical giant-cell tumour with no suspicion of malignancy at all.

In June 1934 surface application of radium was made so as to destroy by its radiations any more tumour tissue that might be present. X-rays have been taken every month or once in two months regularly and a little honeycombing is found to persist on the outer aspect. I am inclined to think that this is due probably to the muscle graft that has been put in. Deep x-ray therapy to the part will help a great deal to drive off any more suspicion of recurrence of the tumour.

Clinically, the upper end of the tibia is now hard with no feeling of any cavity or thinned-out bone, and the movements of the knee joint are quite free. She is walking about now, climbs stairs by herself and is just as strong on her leg as ever before.

Case 3.—Patient C., aged about 45, female, came to the hospital in December 1933 with the history of her right leg giving way while climbing stairs and spraining her thigh muscles. On examination there was a fracture of the middle of the right femur and the history was suggestive of a spontaneous fracture. X-ray confirmed the fracture with slight lateral displacement of the fragments. It further showed an area of rarefaction with cavities in the bone. There was no primary malignant tumour anywhere and the patient was otherwise healthy. A tentative diagnosis of fibrocystic disease was made and an operation advised.

A local excision of the affected part of the bone on both sides of the site of fracture was made and about three inches of bone thus removed. The ends of the bone were brought together and plated. The wound was closed in two layers and the limb put in plaster-of-paris casing including the hip and the foot. The patient had slight temperature of 100°F. for two or three days and had an uninterrupted recovery. In two months she was able to move the limb herself, with a shortening of three inches.

The excised part of the bone showed five or six cysts and the cysts wall showed on microscopic examination giant cells typical of giant-cell tumour. This is probably an instance where the condition started as a fibrocystic disease and developed the tendencies of giant-cell tumour later on. The two are probably different appearances of the same pathological process and it is hard to know where one ends and the other begins. Further evidence is of course required for proof of this.

She was walking about with the aid of crutches and was advised to undergo another operation to shorten the femur of the opposite side. She refused however and was later lost sight of.

Case 4.—Patient D., aged about 25, female, came to the hospital in April 1934 with a hæmorrhagic ulcer on the radial aspect of a swelling of the lower end of the right forearm. The duration of the disease was about six months. The tumour was pear-shaped and of the size of a small orange. It looked like a sarcoma of the lower end of the radius, but x-ray showed an expanded lower end of the radius with the rest of the diaphysis normal. There was discontinuity of the bony shell on the radial aspect where the ulcer was present. The ulna was normal in appearance. Her general condition was on the whole good. A tentative diagnosis of giant-cell tumour of the lower end of the radius was made. The ulcer was dressed with eusol for two or three days and it was then clean.

A week later a local excision of the tumour was done, a bone graft four inches long from the right tibia was inserted and the limb put in a plaster-of-paris pad with the wrist dorsiflexed. The wound however got septic, the graft was dead and had to be removed. The septic wound healed in six weeks and the patient was discharged with a deformed limb. No pathological examination of the specimen could be done.

Two months later the patient came back again with a sarcoma of the lower end of the ulna and the limb was then amputated at the lower third of the humerus.

The initial tumour was a sarcoma to start with and had probably affected the ulna also at the time; or the sarcoma of the ulna may be an independent process altogether. The lack of pathological evidence of the first specimen leaves the whole thing in doubt. The bone graft should have been avoided at the time of the primary operation, because of the ulcerated condition of the tumour and the impossibility of avoiding post-operative suppuration.

Case 5.—Patient E., aged 18, male, was admitted into the hospital in January 1934 with a swelling of the lower end of the left thigh and knee and with a sinus on the internal aspect of the knee exuding pus mixed with a sanious discharge.

The history was as follows:—He had a feeling of numbness in his leg for five months and there was also a swelling in the lower part of the thigh. One day he felt something breaking near the knee joint and was not able to move the joint after that. He went to a

doctor who diagnosed the condition as an abscess probably due to osteomyelitis. He incised on the inner aspect but could get only blood and no pus. He dressed the case for a month and a half and sent him to the hospital. The sinus on the medial aspect was the result of the operation. He had also developed a bed sore over the posterior aspect of the sacrum.

The whole part including the distal portion of the limb was hot, tender and oedematous and looked like cellulitis. He had a temperature of 103°F. on admission with a pulse of 130 per minute and his general condition was very toxic. The swelling was of the size of a big coco-nut, but the upper part of the femur was normal. There was no pulsation of the tumour on palpation. Twenty cubic centimetres of blood-stained fluid were aspirated from the knee joint. A large giant-cell tumour of the lower end of the femur with a pathological fracture were seen on x-ray examination. The tumour had overgrown the limits of the bony shell which only appeared as a few islets on the inner side.

The condition of the patient was so precarious that the only idea was to save his life. The limb was amputated at the middle of the femur and the flaps kept open. It was daily dressed with eusol, and anti-gas-gangrene serum was freely administered to prevent spreading infection. The patient gradually came round and on the 14th day after the operation the wound was closed with a side drain. He put on weight, the wound and the bed sore healed and he was discharged minus his left leg seven weeks after his admission into the hospital. I have heard from him since and he is quite well and has had no recurrence of the trouble.

Case 6.—Patient F., aged 20, male, carpenter by trade, was admitted into the hospital in October 1934 complaining of pain and swelling in the upper third of the right arm. The history was rather interesting. Seven years back he had a fracture of the upper third of the right humerus due to an injury. Three times after that he had fractured the same bone at the same site due to a fall from a camel. This time he was trying to throw a stick at a dog and felt his arm giving way at the same site.

On examination there was a fusiform swelling in the upper third of right humerus extending to the head of the bone. There was also a distinct fracture at the site. The shoulder joint was free. There was no temperature and his general condition was quite good. It was distinctly a pathological fracture.

X-ray showed a pathological fracture due to rarefaction from a cystic condition of the bone. A tentative diagnosis of fibrocystic disease of the humerus was made and the patient advised operation.

A local excision of the diseased portion of the bone left only the head of the bone above and the lower two-thirds of the humerus below with a gap of four inches in between. A bone graft four and a half inches long was removed from the right shin and was put into the medulla of the lower fragment below and into a scooped out cavity on the distal surface of the upper fragment above. The wound was then sutured in three layers with interrupted stitches and dressed. The whole of the upper right extremity was then put in plaster-of-paris casing with the limb in the 'aeroplane' position.

Pathologically the specimen removed showed distinct areas of giant-cell tumour and other areas of fibrocystic disease.

The patient had a temperature of 101°F. for three days and gradually came down to normal. He was able to sit and walk about in a week's time with the limb still in plaster. After six weeks the plaster was cut, the sutures removed and the limb put up in the same position in a gutter-shaped plaster pad applied only to the under aspect of the arm so as to support it, but the patient was allowed to try to lift the limb up from the pad once a day. Passive and active movements were started regularly a fortnight later. In another three weeks the splint was left off and the patient instructed to move the shoulder as much as possible with the help of the other hand, and to keep the arm to his

PROPHYLAXIS OF CHICKEN-POX BY INOCULATION WITH VESICULAR FLUID

By R. C. WATS, M.D., D.P.H., D.T.M.
MAJOR, I.M.S.

and

N. P. DALAL, M.B., B.S., D.P.H., D.T.M. & H.
(Haffkine Institute, Bombay)

THE majority of those in touch with chicken-pox consider it unnecessary to employ any prophylactic measures against the disease owing

(Continued from previous column)

side while sleeping. X-rays were taken at regular intervals. The graft was getting organized and the humerus becoming a solid whole. There was ankylosis at the shoulder joint and the movements of the head in the glenoid cavity of the scapula were getting restricted. However the scapular movements on the chest wall were making up for the loss of shoulder movements. He was discharged in May 1935 with no pain and the movements fairly free, but for the limitations at the shoulder joint as explained above. He was able to lift things with the right hand and to do light work. He came back again three months later and showed that he was able to do more heavy work with that hand. He was looking forward to do his carpentry work.

Conclusions

1. The direct relationship between the giant-cell tumour and the localized fibrocystic disease is shown and both the pathological conditions may be found in different parts of the same tumour.
2. The difficulty of differentiating the giant-cell tumour from an osteogenic sarcoma is demonstrated, especially when the tumour has ulcerated on to the surface.
3. The appearance of sarcoma in the adjacent bone after a tentative diagnosis and consequent local excision of the giant-cell tumour in the other is described.
4. The possibility of saving the limb by means of a bone graft where otherwise the limb would have been amputated is proved.
5. The need for amputation still exists in really hopeless cases.

N.B.—These cases were under my care when I was the Principal Medical Officer of Bikaner State, Rajputana, India.

to its mildness and rapid spontaneous recovery. In some cases, however, the contagiousness of the disease interferes so much with the normal routine that the work comes to a standstill. As an example we might quote the instance of a training battalion in India, where the majority of the recruits were either suffering from the disease or were isolated as contacts. In such cases any practical method for prophylactic purposes would be very desirable.

Greenthal (1926) vaccinated 36 contacts with vesicular fluid from a case of chicken-pox; 19 of these showed a typical vesicle. None of the cases developed the disease but, as there were no controls, the experiment was inconclusive. Waddell and Eley (1927) vaccinated similarly 23 contacts, eight of whom developed the typical vesicle. There is no mention of controls in the series and it is quite probable that the majority of the vaccinated people were immune already as only 33 per cent developed the typical vesicle. Hisse and Unger (1928) injected 38 children intravenously with vesicular

Difference in the technique adopted.—There is, however, one noteworthy difference between the technique referred to in the literature above and our own. In the former case the vesicular fluid was taken as such but we have filtered the diluted material in a Chamberland L3 candle to safeguard against any pyogenic infections. We have recorded this fact as we are not sure what effect the filtration has on the virus.

Experiment I

Material employed.—(1) The vesicular fluid was collected from two cases on the fourth day of the disease, suitably diluted to make a 20 per cent dilution with normal saline and filtered through a Chamberland L3 candle. (2) Normal saline (0.85 per cent).

Procedure.—An intradermal injection of 0.2 c.cm. of the appropriate solution was given on the left forearm.

Table I summarizes the result of the experiment.

TABLE I
Age group 14 to 18 years

Material employed	Total number inoculated	Local reaction	REMARKS
The vesicular fluid. 20 per cent.	64	Twenty-one (33 per cent) had erythematous patches slightly raised measuring on an average 1.5 centimetres.	Five of the 21 had headaches in addition to local reactions.
Normal saline ..	10	Three (33 per cent) had erythema as above.	No headache.

fluid after suitable dilution. Angarano and Gabriele (1931), following Fabris' technique, employed pure vesicular fluid as well as a 20 per cent dilution of the vesicular fluid intradermally for prophylactic purposes. The total number of cases thus protected was 12 with three controls. As two of the latter developed the disease there is some evidence that such a procedure may be of some value, but the number of cases is rather small.

A mild outbreak of chicken-pox was reported from I. M. M. T. S. 'Dufferin'. The first case reported sick on 13th February, and up to 31st March, 1936, there were 15 cases altogether. On the advice of the port health officer, it was decided to use the intradermal method, referred to above, to protect the contacts. Normal saline was injected for control purposes.

The controls as well as the vaccinated were observed for nine months but none contracted chicken-pox.

Experiment II

In the following experiment an attempt was made to ascertain if the serum from chicken-pox cases could be substituted for the vesicular fluid. The serum which was left over after the Wassermann test of the two cases (see experiment I) was diluted with normal saline to give a concentration of 10 per cent and filtered through a Chamberland L3 candle. Normal saline was used as control. An intradermal injection of 0.2 c.cm. of the appropriate solution was given on the left forearm.

The results are tabulated in table II.

TABLE II

Age group	Total number inoculated	Local reaction	REMARKS
(a) Inoculated with the serum (10 per cent).			
14 to 18 years ..	21	Seven (33 per cent) had erythema as in experiment I.	No headaches.
20 to 50 years ..	44	Eight (17 per cent) had erythema as above.	Do.
(b) Inoculated with normal saline.			
14 to 18 years ..	10	Three (33 per cent) had erythema as above.	Do.
20 to 50 years ..	48	Eight (17 per cent) had erythema as above.	Do.

The controls as well as those vaccinated were observed for nine months but none contracted chicken-pox.

Summary and conclusion.—As there were no cases after the inoculation in any group, the value of the prophylactic measure cannot be gauged. It is evident that neither the vesicular fluid nor the serum of the patients collected on the fourth day, diluted and filtered as above, was capable of producing the disease after an intradermal inoculation. Amongst the vesicular-fluid group about 8 per cent had headaches in addition to the erythema, the other groups being free from this symptom.

This note was written as there seems to be a general impression that vaccination with the vesicular material checked the epidemic on board I. M. M. T. S. 'Dufferin'.

A Mirror of Hospital Practice

FATAL CASE OF ACUTE GONORRHOEA (SEPTICÆMIA WITH ULCERATIVE* ENDOCARDITIS)

By P. V. KARAMCHANDANI, M.B., F.R.C.P.E.
 MAJOR, I.M.S.

Officer in charge, Brigade Laboratory, Mhow, C. I.

RIFLEMAN N., aged 29 years, exposed himself to infection at Indore on 27th October, 1935, and noticed a urethral discharge on 29th. About the 12th November he noticed a papule on the dorsal aspect of the penis under the prepuce, which eroded and formed into a sore before his admission to the Indian Military Hospital, Mhow, ten days later.

The sore, on admission, was found to be indolent and painless, with surrounding infiltration. Urethral discharge was purulent, yellow and thick. Epithelial

He was given the following treatment:—

1. Milk diet and barley water freely.
2. Potassium permanganate lavage 1 in 20,000 B.D. (anterior irrigation pint 1, posterior pints 2, strength to be gradually increased to 1 in 8,000).
3. Calomel grs. 2 at bed time. Mist. salina oz. 1 next morning.
4. Hot fomentations over the bubo four-hourly.
5. Saline dressing over the sore.
6. Tincture belladonna min. v
 Potassium citrate grs. xv
 Potassium bicarbonate grs. xv
 Tincture hyoscyamus min. xv
 Infusion buchu to oz. 1

Sig. oz. 1, t.i.d.

23rd November.—Blood film was negative for malarial parasites and the dark-ground examination of exudate from the sore on the penis revealed no spirochaetes.

cells, gonococci and pus cells were in large numbers, the last being in great excess, which suggested that he had had gonorrhoea for three weeks without treatment. He had a bubo in the right groin, without signs of acute inflammation or redness of the overlying skin. Spermatic cords, testicles, Cowper's glands, prostate and seminal vesicles showed no abnormality. There was nothing abnormal in the urine except that the 2-glass test showed turbidity in both glasses, indicating anterior and posterior urethritis.

His temperature was 99°F., pulse 76 per minute, respiration 18 per minute. There was nothing abnormal in any of his systems. He had a roseolar rash, pinkish in colour, extending over trunk and limbs, more marked on the latter, it looked like the preapular rash of early secondary syphilis.

* Abridged by Editor.

Until the 3rd December the patient had no special complaint. Rectal examination revealed no enlargement or tenderness over the prostate. His temperature kept normal except for rises on 24th, 25th and 29th of November which was probably due to the rash. The blood was strongly positive to the Wassermann reaction on 26th November.

On the 3rd December, patient had a sudden rise of temperature to 103°F., complained of discomfort on micturition with increased frequency. Urine showed turbidity in all the four glasses. He was given a dose of saline mixture and alkaline mixture four-hourly.

Barley water and glucose water (5 per cent) not less than 4 pints in 24 hours.

Next day the patient developed prostatitis. He looked definitely ill. Urethral discharge had diminished, and the smarting sensation during micturition had

increased and his prostate was found to be tender on rectal examination. His blood showed no malaria parasites and the differential leucocyte count was: polymorphonuclears—70 per cent, lymphocytes—23 per cent, large monocytes—7 per cent.

Lungs were clear, heart showed nothing abnormal, liver and spleen not enlarged.

He was given (1) urodonal 1 drachm three times daily, (2) hot Sitz bath for 20 minutes twice a day, (3) rectal lavage with boric lotion (temperature 116°F.) directed on the prostate, three times a day, (4) hot fomentations to perinæum four-hourly. All routine urethral treatment was stopped. He showed no improvement, developed aching pains in the chest and limbs and was put on 'S. I.' list on 6th December.

By 7th December he had developed vesiculitis and orchitis, and was given (1) suppository of atropin gr. 1/75 with extract belladonna gr. 1/4 at bed time, and (2) application of glycerine-belladonna locally over testicles.

Up to the 10th December the patient felt better and micturition was easy. But that was perhaps the period when migration and settlement of infection was occurring in distant parts, because on the 11th he developed acute arthritis in the right knee joint. There was no swelling or effusion, but great pain on movement of knee joint.

Sulpharsphenamine 0.12 gramme was given intravenously and antiphlogistine applied over knee joint.

On 12th December both the knee joints were painful, while on 16th arthritis had extended to all the joints of the body, the knees, shoulders and right elbow being the worst. Blood was taken for culture on 14th December and gonococci were isolated.

Sitz baths and rectal douches were stopped and mixed vaccine (gonostaphylococcal) 1 c.cm. (first dose) was given subcutaneously.

On 17th the patient developed endocarditis as revealed by a localized presystolic murmur. Heart was not enlarged. From now on the patient gradually got worse, became toxæmic and exhausted.

On 20th he developed intense pain in his cardiac area and auscultation revealed crepitations of pleuro-pericarditis; spleen became tender and enlarged; temperature high, regular quotidian intermittent type (see chart); and pain became generalized all over his body. There was no evidence of myocarditis.

On 22nd December gonococcal serum 22 c.cm. was given in the morning and patient placed on 'D. I.' list.

At 3 p.m. patient suddenly became unconscious with conjugate deviation of eyes to the right (indicating a cerebral lesion on the left side). Pupils were dilated and insensitive. Pulse was full, 134 per minute, and respiration hurried, 40 per minute. This sudden apoplexy without any prodromal symptoms in the presence of an obvious endocarditis involving the mitral valve pointed to cerebral embolism.

On the following day he developed paralysis of the muscles of deglutition and had an unconscious evacuation of urine in bed. He remained unconscious, and died at 4-10 p.m. on 24th December, 1935.

Post mortem was performed at 9-30 a.m. the next morning.

Findings:—

Heart.—Pericardial sac contained turbid fluid (commonly associated with infections of blood stream).

Epicardium.—Patches of whitish appearance of varying sizes up to half an inch square looking more like 'soldier spots' than 'milk spots'.

Endocardium.—Warty excrescences varying in size from a pin's head to a bean present on the auricular surface of mitral cusps, a short distance from their margins and spreading on to corde tendinæ; muscili papillaris swollen and inflamed; no extension over mural endocardium or intima of aorta; vegetations of crumbling type; aortic cusps normal in appearance.

Lungs.—Crepitant and floated in water.

Left lung.—One abscess at the cardio-pleural junction, apparently the cause of the pain which patient complained on 20th December, over which crepitations were

heard on auscultation. There were two more abscesses in the lower lobe (posterior aspect). The abscesses were surrounded by an area of secondary inflammation. Smear of pus from the abscess at the pleuro-cardiac junction showed Gram-negative diplococci resembling gonococci.

Liver.—Slight increase in size. On section it was found to be in the advanced stage of cloudy swelling that is seen in septicæmia and ulcerative endocarditis. The substance of the liver was soft and its tissue yellowish. No areas of necrosis discernible to the naked eye.

Spleen.—Swollen and soft in consistence. On section it had a pinkish creamy colour with white infarction present in its upper half.

Kidneys.—Appeared normal.

My excuse for publishing this case is its comparative rarity, its failure to respond to routine treatment, and the regular march of complications from posterior urethritis to cerebral embolism. The failure to respond to treatment may have been partly due to the syphilitic infection which the man had apparently contracted concurrently with the gonorrhoea.

MALIGNANT DISEASE OF THE PROSTATE IN A SMALL CHILD

By RAI BAHADUR HUKAM CHAND GUPTA
F.R.C.S. (Edin.)

Civil Surgeon, Mardan, Peshawar, North-West Frontier Province

A MALE child, about 3 years of age, was admitted into the Lady Reading Hospital, Peshawar, on the 16th September, 1936, with difficulty in micturition, which had existed for 15 days. There was no history of any trouble previously. The child was well developed for his age but looked rather pulled down and had a temperature slightly above normal. Stone in the bladder was suspected so he was to be prepared for operation.

On the 18th September he was anaesthetized; his bladder was sounded; no stone was felt but only a peculiar rough, feel of the bladder wall. As there was a very definite history of painful micturition, the bladder was opened suprapubically. A hard nodular growth was felt around the internal urethra. The prostate was also felt through the bladder to be enlarged. The growth was very hard and a few of the nodules were scraped out for examination. The bladder was drained suprapubically and the wound closed.

The prostate was very enlarged and hard when felt per rectum. There was no hæmaturia. A provisional diagnosis of sarcoma of the prostate with involvement of the bladder was made, awaiting confirmation from the laboratory.

The nodules that had been removed were sent to the Provincial Laboratory for report. Lieutenant-Colonel W. E. R. Dimond, I.M.S., kindly examined the material and reported it to be a case of early malignancy.

The wound healed perfectly but had to be kept open for purposes of micturition as no urine was passed per urethram. The child was discharged from the hospital a month after.

I have since learnt the child died one month after discharge from the hospital and no post mortem was done owing to the difficulty of obtaining permission from the parents.

This case is of interest on account of the rarity of such a condition in so young a child.

Indian Medical Gazette

MARCH

DIET AND ADAPTATION TO THE TROPICS

THE problem of the adaptation of man to the climatic conditions of the tropics is a wide one. Its study is of interest not only to those in tropical countries but also to others in the temperate zone, for the real significance of one's surroundings in any climate is never fully appreciated until they are changed. The adaptation that man is called on to make in the tropics is primarily one of heat regulation. This physiological adjustment includes a number of factors, such as dwellings, clothes and food, all of which are intimately concerned in the maintenance of that peculiar mammalian feature, namely, a constant body temperature characteristic of each species, and we do not know whether Nature has provided anywhere in the tropics the ideal local conditions necessary for the maintenance of this body temperature. As regards housing and clothing for instance, man himself can do much in the way of adaptation. Food however is in a somewhat different category. Nature provides a varied dietary which man according to his tastes and customs takes or rejects, but we are not yet clear as to what is the optimal or ideal to be aimed at in order to effect a suitable adjustment to the climate.

The problem of diet however cannot really be divorced from that of heat regulation and body temperature. At the present time nutritional studies in this country are concentrating on the adjustment of diet to disease and its prevention. The calories for the time being are in abeyance, yet this is an aspect that should and would receive due attention were there no evidences of nutritional disease to overshadow it.

Man and indeed each mammal species have set themselves at a constant body temperature somewhere in the region of 100 degrees Fahrenheit, whether they live at the poles or the equator. In general, this temperature is maintained by a more-or-less constant, basal metabolism, aided by a physical mechanism which regulates heat loss by conduction and evaporation of water. *A priori* one would have expected that Nature, were body temperature of prime importance, might have endowed man with the capacity for lowering his basal metabolism under certain conditions. It is not so, however, for it appears that adjustment of body temperature has been effected largely by extrinsic factors, such as housing, punkas, clothes and diminished food intake. Nature

appears to demand that we keep up a body temperature of 98 and a basal metabolism of about 39 calories per hour per metre in whatever latitude we may find ourselves. To ask 'why' is hardly a justifiable question; science is concerned only with the 'how'. Some years ago, at a meeting of physiologists in the United States of America, it was suggested that all the mammals had met in the garden of Eden and had decided after discussion to set their temperature and metabolism at that level. In such a flippant manner does the scientific mind react when confronted with a 'why'. Barcroft, however, has pointed out in his *Features in the Architecture of Physiological Function of the Living Body* that the constant temperature and composition of the blood is really an essential condition for the normal functioning of one activity—namely, consciousness. Lower the temperature or the oxygen of the blood beyond a certain point and consciousness is the first to suffer.

The problem however of the suitability or otherwise of a tropical food to the tropical climate is not so easily solved nor are we given so obvious a lead as is the case with housing and clothing. Nature offers fat and protein at the poles and carbohydrates at the equator, and willy-nilly man has accepted what has been given to him. Buckle, in the middle of last century, in *History of Civilization* gives an interesting comment on the significance of fat in the arctic regions. As is well known, fat has a higher caloric value than the other foodstuffs and requires a greater amount of oxygen to oxidize a given weight compared with carbohydrate. At the poles he points out that each breath of inspired air (at the temperature prevailing) carries more oxygen than a corresponding volume of air in the tropics and hence a greater amount of fat can be oxidized. This explanation is perhaps hardly relevant, but the attitude of mind is prophetic of the modern work of L. G. Henderson who has done so much to show the fitness of the environment in relation to the needs of the organism.

The heat-stimulating effect of protein—its specific dynamic action—is one which does appear to play a part in the adjustment of diet to climate. The Eskimos often consume large quantities of meat, sufficient to raise their metabolism over 50 per cent, an obviously practical advantage. In the tropics, on the other hand, a low-protein vegetarian diet is hence from this point of view advisable. A low-fat diet is also a feature of the tropical dietary and within limits probably advantageous. On account of the low-protein diet and a climate making extreme physical work almost impossible, a large calorie intake is never required; in other words one's calories can be supplied without undue bulk in the form mostly of carbohydrates. In the colder parts of the

world where harder physical work can be and often is performed, the calorie intake of a Canadian lumberman for instance, which may be 9,000, could not be consumed as starch without putting too much strain on the demands of the alimentary canal. Such a diet would be almost impossible were it not that fat is very much less bulky than cereal foods, etc. The tropics do not demand an unduly large layer of body fat externally or internally, hence there is a further diminished demand for fat.

Carbohydrates, however, have a definite effect on the physiological mechanism of the body, which seems to be of considerable importance. Numerous workers (Zuntz, Bridges, Puckett and Wiley) have noted that a change from a fat to a starch diet involves a considerable retention of water and *vice versa*. Some of this is taken up by the stored glycogen and some as extra fluid in the extracellular, and probably intracellular, fluids. In other words on a carbohydrate diet there is an increased reservoir of water for evaporation and urine secretion if necessary. Moreover, carbohydrates are always the first to be metabolized and hence *pari passu* more mobile fluid is available while it is being burnt. Further, experiments by Burr and others on rats on a fat-free diet have shown that those animals consume more water and excrete actually less urine than others with fat in their diet. More fluid appears to be eliminated by the skin and lungs. It may be a small point but pulmonary ventilation is greater when carbohydrate rather than fat is being burnt, owing to a larger output of CO_2 per calorie of heat. This would increase the heat loss by evaporation of water by the lungs.

These experiments are suggestive in the light of the observations of Eijkman in 1924 on Europeans and Malaysians in Java. He noted

that the Malayan is much more economical (physiologically) in his water elimination than the European. Under identical conditions a European lost 143 grammes of water and a Malayan only 105 grammes by insensible perspiration in a given period. Contrary to expectation, the Malayan had also the smaller volume of urine, even though he had received extra water, while the European had been deprived of it during the observation. The European appears to waste water as liquid perspiration which hence does not perform its physiological function—namely, evaporation and heat loss. It is then a problem how much of this adaptation is racial and how much is due to a carbohydrate diet conserving the body fluids. The increased urine elimination of the European may have been due to the greater quantity of nitrogenous products, which would be much less in the Malayan consuming a low-protein diet. The Malayan on the other hand may consume more salt, which, under certain circumstances, promotes retention of water.

Such then are some of the ways in which Nature may have been more beneficent to those at the equator than one thinks. One does not wish to make out an apologia for the time-honoured dietary of thousands of years which nevertheless does seem to lack certain essentials necessary for health. Yet it should be said that it points to the necessity for due caution in laying down nutritional standards which are merely carried over from a temperate zone. Man is an adaptable animal, and, if a healthy body fabric is to be woven, let the warp be made from scientific principles and the woof from the customs and habits of the peoples in whatever region of the world they may be situated.

THE EPIDEMIOLOGY OF LEPROSY*

By JOHN LOWE, M.B., Ch.B.

(Research Worker in Leprosy under the British Empire Leprosy Relief Association, the I. R. F. A., and the School of Tropical Medicine, Calcutta)

1. Introduction

In this paper I attempt to outline in a general way some of the chief facts and theories regarding the epidemiology of leprosy. I am, however, not an epidemiologist, and also knowledge of this aspect of leprosy is not very extensive or accurate.

Epidemiological studies of leprosy are handicapped because statistics collected by health authorities, census officers, etc., are so inaccurate as often to be very misleading, and also because we have no test which indicates with any accuracy susceptibility or immunity to leprosy. The leprosy worker has to collect his own information and statistics by direct observation of the disease in the peoples affected.

The epidemiological study of any disease involves a study of its history. Leprosy is a disease which is constantly referred to in literature from the most ancient times to the present day, and from a study of these records classical scholars have tried to piece together a history of the disease. The following is an outline of this history based largely on that given in Rogers and Muir's *Leprosy*.

* A paper read at the Public Health Society, Calcutta, 22nd January, 1937.

2. Outline of the history of leprosy

This outline is of doubtful accuracy. The disease possibly originated in Africa. In pre-historic times it spread to India and Egypt and a very early reference to it is in the Vedas dated about 1400 B.C. In the Eber's papyrus about 1550 B.C. there are descriptions of skin diseases under the names 'Uchedu', 'Chon's swellings' and 'Anut of Chon's swellings', the symptoms of which correspond very closely to those of leprosy. There is a questionable reference to it in the Egyptian records of 1350 B.C. in the reign of Rameses II. Munro reads the records as indicating the presence of leprosy in Negro slaves brought from the Sudan. Whether this reading is accurate or not, there is no doubt that in ancient as well as modern times invasions and the slave trade have been important factors in the spread of leprosy from one country to another.

Thus in very ancient times leprosy was common in Central Africa, India and possibly Egypt and in these areas it is common to this day.

From India leprosy spread eastwards. The oldest Chinese medical writings give no definite indication of its presence, but in the writings of about 100 to 200 B.C. there are definite references to leprosy.

From Egypt the disease spread round the eastern Mediterranean. The Jewish writings of the Bible contain many references to a disease 'Zaraath', which is described in some places in the Bible as being highly contagious, producing patches white as snow, and being fairly readily curable. Other references in the Bible indicate the incurability of leprosy. Possibly under the one term 'Zaraath' are included many skin diseases, such as psoriasis and leucoderma, as well as leprosy.

In 150 B.C. when the Jewish writings were translated into Greek, the word *Zaraath* was translated into the Greek term 'lepra' which is used in the Hippocratic writings for a scaly disease. It is probable that in the Hippocratic era there was no true leprosy in Greece for Hippocrates described no such disease, but Aristotle about 345 B.C. has references to the disease which may, therefore, have been found only in Asia Minor. Factors which may well have contributed to the spread of leprosy were the conquest of Egypt by Cambyse, 525 B.C., the conquests of Darius in the same century and later in 480 B.C. the conquests of Xerxes. According to Herodotus, Xerxes led 6,000,000 people from Asia into Europe, many thousands of whom remained in Europe. When true leprosy appeared in Greece the term 'lepra' was not applied to it but the term elephantiasis was used. The use of the word 'lepra' for what we now know as leprosy probably originated in a mistake in translation. In early medical writings in Arabic the term 'djudsum' is used for leprosy, and when these writings were

translated into Greek by Constantine of Carthage in the tenth century, the word 'lepra' was wrongly used, but the name has stuck. The Greek term for leprosy, elephantiasis, is still used in some medical writings and in Calcutta when the diagnosis has to be written without the patients or others knowing the initials E.G. (Elephantiasis Graecorum) are often used.

Leprosy was unrecorded in Roman writings until the time of Pompey, when it is recorded as having occurred in the soldiers returning from the East in 62 B.C. In Roman history from then onwards leprosy is often referred to. The Romans introduced leprosy into other parts of Europe. Galen wrote of it in Germany in A.D. 180 and Virchow reports that by A.D. 600 there were hundreds of leper houses in Italy and Germany. In the fifth and sixth centuries Spain was infected by Roman troops. After the fall of Rome, the conquest of Alaric and others probably helped to spread the disease. From Spain leprosy spread to France. (The Saracens invaded France from Spain early in the eighth century.) In 1757 laws were passed prohibiting the marriage of lepers and decreeing divorce of lepers.

Leprosy was probably introduced into England by the Romans. Sir G. Newman records that the first leper house in England was founded in Nottingham in the seventh century. The following are the dates of the establishment of the first leper houses:—Ireland 869, Wales 950, Scotland 1177 or 1300 (Newman). Meanwhile Norway was infected in 1266 and Shetlands, Faroe, Iceland, Greenland, Holland, Denmark, Sweden, Russia, the Baltic countries had also been infected.

Leprosy reached its height in Western Europe about 1200 though it was very common from A.D. 1000 to 1400 (2,000 leper houses in France alone). The influence of the Crusades on the incidence and the spread of leprosy has been discussed, but Newman thought that they only affected leprosy by impoverishing western Europe.

So far the story has been one of the introduction of leprosy into previously unaffected countries, and of its spread in such countries. In the thirteenth century, however, leprosy began to decline in Western Europe and by the seventeenth century it had more or less died out in this area excepting in a few persistent foci. The 'epidemic' in Europe had lasted about one thousand years.

The reasons for the dying out of leprosy in Western Europe have been discussed at great length by various writers, but no really satisfactory explanation has been given. Some students of the subject have considered that the isolation carried out in 'leper houses' was responsible (there were thousands of such institutions in medieval Europe). Climate and meteorological changes have recently been quoted as

important factors. Improved social and hygienic conditions and diet have been cited. A few writers have suggested that the Western European races gradually became immune because of the gradual dying out of the stock which was susceptible to leprosy. Other writers have considered that the tremendous mortality associated with the great plagues of the Middle Ages was an important factor. Some of these factors are discussed later. Other writers think that the reasons for the decline of leprosy in Europe are undetermined and possibly undeterminable, and quote similar phenomena seen in other diseases, such as tuberculosis and plague, such diseases dying out gradually or suddenly with no apparent cause, sometimes when conditions appear to be most favourable for their spread. One striking example of this is the steady decline in tuberculosis in England which began about 1800 just when the industrial revolution created conditions apparently favourable to its spread. This decline started long before the establishment of any organized anti-tuberculosis work.

I think we must admit that we have no satisfactory explanation of the decline of leprosy in Europe.

While leprosy was declining in Europe it was being conveyed to other previously uninfected countries: to North America and the West Indies by immigrants from Europe and by slaves from Africa, and to South America by immigrants from Spain. In South America leprosy is still widespread, but in North America there are only a few foci of leprosy.

Even within the last half century leprosy has been introduced into previously uninfected countries, chiefly Pacific Islands. The story of leprosy in Nauru is well known to students of leprosy. Leprosy was introduced and for some years spread very little. After the influenza epidemic of 1918 however (in which an incidence of 100 per cent and a mortality rate of 30 per cent were seen) leprosy spread widely and in a few years about 20 per cent of the population was affected, the disease, however, being in a comparatively mild form. The epidemic was short-lived and is now on the decline.

The history of leprosy is, on the whole, a history of endemicity of the disease in some parts of the world for thousands of years with its introduction from time to time into other parts where it may be seen in the form of very long period epidemics, dying out in time for no apparent reason.

3. *Transmission of leprosy*

This matter can only be discussed very briefly here. The only mode of transmission of leprosy about which there is any certainty is transmission by direct contact with infectious cases. Even so we do not know the exact way in which the bacilli get into the body, but most workers

consider that it is probably through abraded skin or through mucous membrane.

Transmission by contact with infected articles may be seen occasionally. It is extremely doubtful if the disease can be conveyed by infected air, water or food. Insect transmission appears on the whole to be improbable.

4. *The present distribution of leprosy in the world*

Leprosy is now regarded as a tropical disease and it is found chiefly in tropical countries but it still exists to a considerable extent in some non-tropical countries and, as will be clear from the history of leprosy which I have given, it used to be very prevalent in many non-tropical countries. The present distribution of leprosy in the world is shown roughly in the accompanying map I. Light shading indicates presence of leprosy but in small amount, less than 1 per mille. The more heavy shading indicates a moderate incidence of leprosy, probably between 1 and 2.5 per mille. The black portion indicates an incidence of leprosy of more than 2.5 per mille. In the black areas the incidence is usually from 5 to 10 per mille but in some areas, such as portions of Central Africa, the incidence may rise as high as 50 per mille. The map shows that the chief foci of leprosy are Africa, India, China and South America, that the heavily affected areas are nearly all in the tropics but that leprosy is found sometimes a long way from the tropics and even inside the Arctic circle, for example, Greenland, Iceland, Norway, the Baltic countries and Canada.

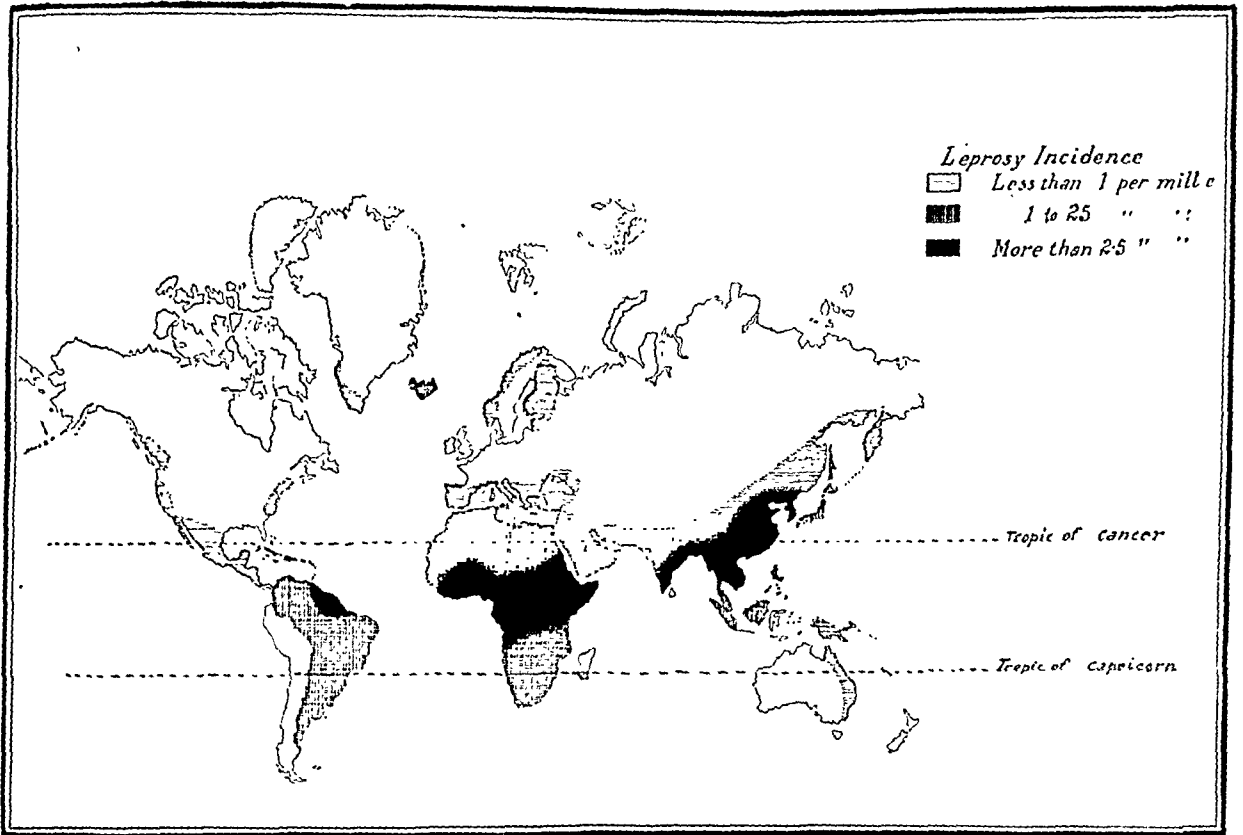

5. *Distribution of leprosy in India*

This is shown roughly in the accompanying map II. It will be seen that the areas with a high incidence are in the east and south, that central and western India and the Himalayan areas show a moderate incidence while the north-west of India is relatively free from leprosy. The most heavily affected areas are probably West Bengal, South Bihar, Orissa and Madras.

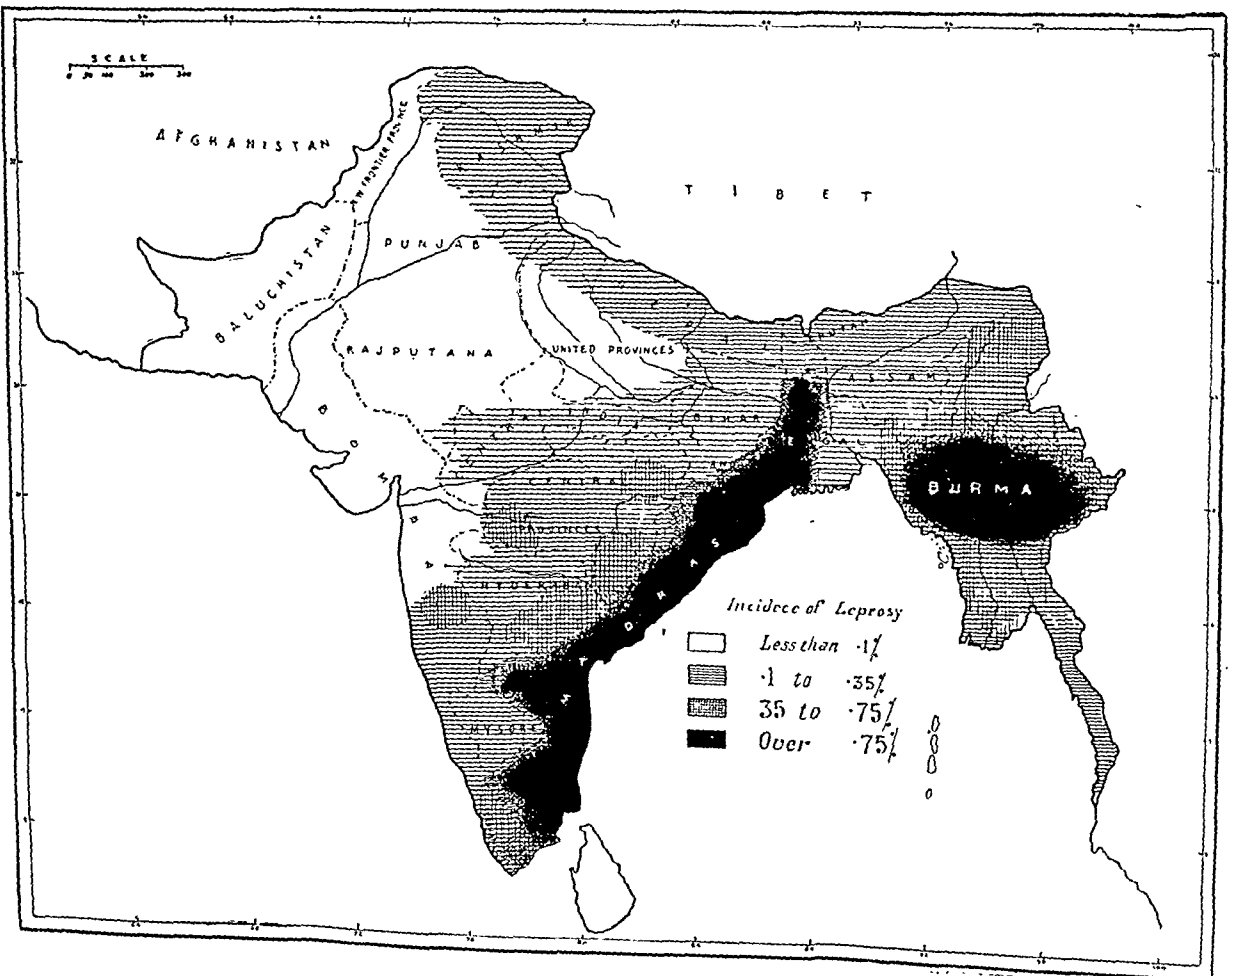

6. *Incidence*

Until about 10 years ago the only information regarding incidence of leprosy in India as a whole was that available in the decennial census, which in 1921 reported a total number of 102,000 cases of leprosy, giving an incidence of .35 per mille. The highest incidence reported in any area was about 1 per mille. During the last 10 years much leprosy survey work has been done in various parts of India and it is found that the census figure for many areas needs to be multiplied by a factor which varies between 3 and 20 and averages about 8. The census return for 1931 shows a figure of 147,911, an increase on the 1921 figure of 45,398. This increase possibly does not represent a real increase of leprosy but only an increase in the accuracy of the return. On the basis of our survey findings we have concluded that the

MAP 1

MAP 2

GRAPH 1

GRAPH 2

GRAPH 3

GRAPH 4

number of cases of leprosy in India is probably not less than one million. We find, in the heavily infected parts, large areas where the incidence may be 2 per cent of the population. We find small areas where the incidence is 5 or 7 per cent. We find villages in which the incidence is 15 or 20 per cent. It is on the basis of these survey figures that the accompanying map II has been made.

7. *Types of leprosy*

These high figures should however be explained a little. In survey work in India we find that on the whole there are about two relatively mild cases of leprosy to every severe case. In some of these mild cases, the disease is of little clinical or public health importance and in quoting these high figures these facts should be borne in mind.

8. *The age distribution of cases of leprosy*

The age distribution of cases of leprosy in India reported in the 1921 census is shown in the accompanying graph 1. The highest number of cases is found in the middle age periods. This graph is, however, of little value in indicating the age in which the disease is contracted because leprosy is a very chronic, often non-fatal, disease which exists for many years, and a middle aged or old person suffering from leprosy may often have contracted the disease quite early in life. An indication of the age at which the disease is contracted is given in graph 2 which gives the age at which the first symptoms were noticed, in 400 unselected cases of leprosy of all ages. It will be seen that in most of the cases the symptoms were recognized by the patient before the age of 30. Slight symptoms of leprosy may be present for years before they are recognized, and also the latent period of leprosy is long, averaging possibly three or four years, so that when these facts are taken into consideration, this graph indicates that the disease is probably contracted in the great majority of cases either in childhood, adolescence or early in adult life. The chances of the disease being contracted after the age of thirty are remote, though such cases are seen rarely. The difference in susceptibility at different ages is shown by a study of leprosy in families. Adults exposed to infection show an incidence of about 5 per cent, while children similarly exposed to infection show an incidence of 50 per cent or more. Another finding which is made from a study of leprosy at different age periods is that leprosy contracted early in life is far more likely to take a serious form than when contracted later in life.

9. *The sex incidence of leprosy*

It is a curious and interesting fact that in every country where leprosy is common the number of males suffering from the disease is much greater than the number of females, the proportion averaging about 2 to 1. It may be

thought that these returns are due to the difficulty of examining women properly, particularly in such countries as India, but I think there is no doubt that this is not so. Similar returns are made where there is no difficulty whatever in examining women. For example, in New Guinea, where males and females always wear the minimum of clothing and where the whole population is periodically examined naked for leprosy, the incidence in males is twice as high as in females. In the same area it is found that the disease also tends to take a milder form in females than in males. Similar findings have been reported in many other countries. It therefore appears to be quite definite that males suffer from leprosy more commonly and probably more severely than do females.

It is interesting to study the sex incidence at different age periods. This has been done in various centres. It is found that in the early years of life the incidence in the two sexes is about the same and in some countries it has been found that after the age of puberty the incidence in females may actually exceed the incidence in males. Shortly after puberty, however, the incidence in females reaches a peak and then tends to fall quickly, while at the same period the incidence in males continues to rise for several years and then falls but much more slowly. A graph of the sex incidence of leprosy at different age periods has the form shown (see graph 3).

It is very difficult to explain the difference in incidence and severity of leprosy in the two sexes. We might for a moment consider the question of the sister disease, tuberculosis. I have reproduced here a graph 4 made by McNalty indicating the mortality rate from tuberculosis, of the two sexes at different age periods in England. (McNalty considers that the mortality rate is the most reliable index of the incidence of tuberculosis in the two sexes.) In general outline (if we ignore the early peak due to infant mortality from tuberculosis) the curves are somewhat similar to those of leprosy, the incidence of tuberculosis in females is lower than that of males at all ages except the age of adolescence and the mortality rate is also lower. Now in tuberculosis this difference in sex incidence is probably due chiefly, if not entirely, to environmental factors, namely, greater exposure to infection and to factors which predispose to tuberculosis. This is caused chiefly by industrial conditions in England. Under other conditions the incidence of tuberculosis in the two sexes may be approximately equal; for example, in America, Robinson and Wilson investigated the incidence of tuberculosis in 20,000 industrial workers, 14,000 men and 6,000 women, and found that the incidence in women was slightly higher than in men. In India it is often said that tuberculosis is commoner in females than in males because of the unhealthy condition of seclusion in which many

women live. Therefore the reason for the difference in the sex incidence of tuberculosis is probably environmental. In leprosy, however, it is difficult or impossible to explain the lower incidence in women on this basis. Even in countries where men and women are equally exposed to infection the incidence in women is much lower.

It is a well-recognized fact that women are less susceptible to some diseases than men, but in no disease does this appear to be so marked as in leprosy. An interesting discussion on the sex incidence of the disease in general is given by Stallybrass in his book on epidemiology. I have made the following summary of this discussion :—

There are differences, sometimes quite marked, in the incidence and mortality of infectious diseases in the two sexes. Some diseases (*e.g.*, whooping cough and acute rheumatism) are reported as being more common in females, while others (*e.g.*, pneumonia and the middle-age form of tuberculosis) are more common in males. It is also noticeable that the sex incidence of disease often varies with age.

Nevertheless, at all age periods males show a greater incidence of infectious disease and a higher total mortality rate. This difference may be due to greater exposure or to greater susceptibility. Greater exposure may possibly explain the greater mortality in males in adult life, but it is difficult to see how it can explain greater mortality in childhood. Greater susceptibility in males may possibly be caused by sex differences; males are bigger and have a more developed musculature, which may throw a greater strain on the circulatory and excretory systems and so reduce chances of recovery when attacked. Again it is difficult to understand how this can explain the greater mortality in males in childhood.

The sex factor may be physiological rather than anatomical. The sex hormones are connected with differences in endocrine activity, as shown by the greater activity of the thyroid in women. The endocrine system is intimately connected with destruction of bacteria and their toxins. It is possible that differences in endocrine function in the two sexes may have an influence on the susceptibility to infectious diseases:

In addition to anatomical and physiological differences in the sexes there is the cytological difference. Each cell in the female contains a group of chromomeres different from the corresponding group present in the male, and it is this group that determines sex and sex differences.

Whether these anatomical, physiological, and cytological differences between the sexes have any effect on the sex incidence of disease is uncertain.

To summarize the findings regarding the incidence of leprosy in India, we find that the

incidence probably averages about 3 per mille but in some areas it is as high as 20 per mille, that about two-thirds of cases are relatively mild, that the disease is usually contracted in childhood or adolescence and that males suffer from the disease more commonly than females and tend to show a severer form of the disease.

10. Race and leprosy

It has been suggested that the subsidence of leprosy in certain countries is due to the development of racial immunity due to a gradual dying out of the stock of the race which was susceptible to leprosy. This has been quoted as a possible reason why leprosy died out in Western Europe. Western European races have, however, at the present day no marked racial immunity to leprosy, since cases of leprosy occurring in such persons who go to countries where leprosy is endemic are not uncommon, and this is found in spite of the fact that such persons do not usually go to such countries until the age of the greatest susceptibility has passed. In India, for example, leprosy in Englishmen coming to the country in adult life is not so rare as one might imagine, and when such persons do develop leprosy the disease on the whole appears to take a rather severe form which would not indicate the presence of any marked immunity. It would appear that all races are susceptible to leprosy but there may be minor degrees of natural immunity. It is certainly true that leprosy shows itself rather differently in people of different races. In the Far East, the Philippines, Japan and Siam, for example, the disease appears on the whole to be more severe than it is in India, and also certain clinical manifestations of the disease which may be attributed to the relatively high resistance of Indians to leprosy are much more rarely seen in these Far Eastern countries. These differences may possibly be attributed to climatic and other factors but in countries such as Malaya or the West Indies where the population consists of different races—Chinese, Indian and Malayan, or Indian and African—leprosy appears to show itself in forms varying somewhat according to the race of the affected person. Here climatic and other differences are largely eliminated. It does appear, therefore, that there are some grounds for believing that there are minor degrees of racial immunity to leprosy. Regarding the nature of this immunity I cannot say anything here. The question has been raised as to whether racial immunity to leprosy may partly explain the distribution of leprosy in India. Do the races of the north-west suffer much less from leprosy because they have more racial immunity than the people of the south and east? This is a question which it is impossible to answer. However we find that leprosy is quite common among Punjabis and others who

have migrated to endemic areas such as Bengal, and when it occurs it may take a severe form.

11. *Climate and leprosy*

Climate affects leprosy in two ways. First of all it may affect the transmission of the disease and secondly it may influence the course of the disease. It is certainly noticeable that leprosy is most common in hot humid climates and it is possible that the humidity is of more importance than the temperature. A study of the maps of India and of the world which I have shown indicates how in dry parts, even in the tropics, leprosy is usually uncommon, whereas in moist parts of tropical and non-tropical countries leprosy may be more common. The reasons for this are not clear. One curious thing is that in some countries, where there is a considerable number of imported cases of leprosy, many of them infectious and few of them isolated, examples of such cases infecting others are extremely rare. For example, in England there are probably about 100 cases of leprosy, many of them infectious and many not isolated, but contact cases are extremely rare. The same thing is found in New York city. Climate may also have an effect on the disease and the experience of some physicians who have dealt with leprosy in tropical and in cold countries indicates that a cold country is not favourable for the treatment of leprosy. Thus the climate of countries such as England apparently does not favour transmission of the disease, but it does favour the development of the disease when it has risen.

12. *Diet*

There has, for centuries, been a common idea throughout the world that leprosy is influenced by diet. One of the common ideas in most countries, particularly in India, is that leprosy is connected with the eating of fish. Sir Jonathan Hutchinson took up this idea and gave it as an explanation as to why leprosy was so common in Europe in the Middle Ages when the eating of dried fish was very common, and why a high incidence of leprosy persisted so long among the fisher folk of Norway. Later he modified the idea and said that leprosy was due to eating decomposed fish and other bad food. This idea has now practically no adherents, for leprosy has been found to be common among people who never eat fish. It is, however, noticeable that leprosy does appear to be commoner among those peoples whose diet is ill-balanced. In China, for instance, the disease is much more common in parts where rice forms a staple part of the diet, and where protein, fat and vitamins are little taken. The same is true of India, leprosy being common among the rice-eating people of Bengal, Bihar, Orissa and Madras and less common among the people whose staple diet consists of wheat, *jawar* and other grains richer in protein. Leprosy is also

less common among those peoples in India who take milk or milk products. Similar findings have been made with regard to leprosy and diet in Africa. These things may however be pure coincidence. The difference in the incidence of leprosy in the different parts of India may be explainable on the grounds of racial, climatic and other differences and not of difference of diet. There is no doubt that a good diet is an important thing in the prevention of leprosy and in the treatment of leprosy; but the treatment of leprosy along dietetic lines only has, on the whole, given disappointing results.

13. *Social and hygienic conditions*

There is considerable evidence to show that the incidence of leprosy is markedly affected by social and hygienic conditions and that leprosy tends to die out when conditions are good. The improvement in social and hygienic conditions and diet is given by some as one of the reasons why leprosy died out in Western Europe, but the evidence to show that such very marked improvement occurred between the thirteenth and sixteenth centuries, the period during which leprosy died out, is not very strong.

It is interesting to compare the incidence of leprosy in people in the same country in different stages of civilization. In India, for example, leprosy up to the present has not been common among the aboriginals and semi-aboriginals who live on the whole a healthy out-door life in very small settlements and who, although they are extremely poor, not being vegetarians, often take a much more balanced diet than many other people of India. Also when cases of leprosy occur among them they are commonly ostracized and may be driven out of the community. Thus under primitive conditions in India leprosy is not common. The peoples in India who suffer most from leprosy are the outcastes, the low-caste Hindus and the poorer Mohammedans. I need not here discuss the social and economic conditions which are usually found in the poorer parts of an Indian village, and there seems to be no doubt that these conditions combined with a poor diet and chronic ill nourishment together with the effects of such infections as malaria, chronic dysentery and hookworm have an influence on the incidence of leprosy. We should not, however, imagine that leprosy in India is confined to the lower castes. In the higher castes and among people who have better social and hygienic conditions and who live in better houses and take better diet, the disease is certainly less common, but the disease is actually found in all classes of society in India, from the very highest to the lowest. Cases of leprosy servants infecting others living under good social conditions are far from rare, and it appears that even under the best conditions in India the presence of infectious cases is a very definite menace to healthy people, particularly young people and children.

If we try to correlate the incidence of leprosy in different parts of India with the general, social and economic conditions of the people we find it is not always easy. One of the poorest parts of India is undoubtedly West Bengal and here the incidence of leprosy is high, but it is certainly no higher than it is in some parts of Madras where on the whole the social and economic condition of the people is very much better.

The social and economic conditions of the people are of course intimately connected with diet, and many people do not take a better diet because they cannot afford it. However, a more wise use of the limited economic resources of a family would often improve the diet considerably, and a reduced consumption of carbohydrates and increased consumption of protein, fat and vitamin might render the people less susceptible to infectious diseases such as leprosy.

I think there is no doubt that in India there are two special factors which have an important bearing on the prevalence of leprosy. The first of these is religious sentiment which regards leprosy not as an infectious disease but as a visitation of the gods, a man's fate which cannot be avoided.

Religious sentiment also encourages the giving of alms to beggars, particularly lepers, as a religious duty. This fact encourages the wanderings of enormous numbers of lepers all over India, particularly to centres of religious pilgrimage, and because of this sentiment it is impossible to prevent lepers travelling on trains and public vehicles all over India, usually without any payment.

The second factor is the 'joint-family system' under which a father and mother and all the married sons and their families and all unmarried children share one household. If any member of the family gets leprosy in an infectious form, all the other members of the large joint family are exposed to the infection in the joint-family house, and numbers of them, chiefly children, frequently contract the disease in this way from relatives.

14. Leprosy in rural and urban areas

Leprosy has up to the present been chiefly a rural problem since most of the people in India are agricultural workers living in villages. During recent years the opening up of previously secluded areas by the development of roads and railways, and the establishment of large industrial areas with large numbers of workers recruited from rural areas, have introduced a new aspect of the problem. Healthy workers from rural areas are migrating to industrial centres with their families, there getting infected with leprosy and later returning and spreading the disease in previously unaffected villages.

(Continued at foot of next column)

ALLERGY

By DHARMENDRA, M.B., B.S.

School of Tropical Medicine, Calcutta

IN 1906 Wolff-Eisner suggested that human hypersensitiveness, as seen in hay fever, was related to the phenomenon of anaphylaxis in animals. Meltzer (1910) pointed out the similarity between the bronchial constriction in asthma and that seen in guinea-pigs dying of anaphylactic shock. He concluded that true bronchial asthma was anaphylactic in origin. After these observations all the clinical manifestations of idiosyncrasy were considered as anaphylactic. It was, however, gradually recognized that hypersensitiveness in human beings differed in many important aspects from the anaphylaxis as seen in lower animals. Various terms and classifications have been introduced to cover these differences. Von Pirquet (1911) after studying serum sickness coined the term *allergy* (from *εργον* energy and *αλλος* altered) meaning changed reactivity. He introduced the term allergy to indicate an altered reaction in man to foreign proteins and implied that an antigen-antibody reaction was its basis in general. Later on, Doerr extended the meaning of the term 'allergy' to include all forms of changed reaction to foreign proteins whether any antigen reaction was present or not. The term allergy is now being generally applied to the various forms of human hypersensitiveness exclusive of anaphylaxis in lower animals. Allergy has, thus, now come to mean 'exaggerated susceptibility to various foreign substances or physical agents that are harmless to the great majority of ordinary normal individuals'. The reaction appears after inhalation, ingestion, injection or skin contact of minute quantities of the particular substance and differs from any toxic action the substance might produce in large doses. This hypersensitiveness may be manifested at different sites in the body and these different manifestations are given different names. Thus in the respiratory tract

(Continued from previous column)

Conclusion

These then are some facts and some theories regarding the epidemiology of leprosy in the world and in India. There are great gaps in our knowledge and the need for further study is obvious. There are three points which are clear and although they are elementary they need emphasis. Firstly, leprosy is an infectious disease though not highly infectious, and the conditions found in most parts of India are favourable to transmission. Secondly, while most adults are partly or completely immune to leprosy children are usually susceptible. Thirdly, the most important thing in the control of leprosy is the prevention of contact between infectious cases and children.

we have hay fever*, paroxysmal rhinitis† and asthma‡; in the skin urticaria, giant urticaria, dermatographia, dermatitis venenata and certain forms of infantile eczemas and other skin eruptions; in the gastro-intestinal tract certain forms of gastritis, enteritis, mucous colitis and cyclical vomiting§ in children; in the nervous system certain cases of migraine and epilepsy; in the joints paroxysmal hydrarthrosis and possibly rheumatoid arthritis. Bray (1931) considers certain forms of enuresis in children of allergic origin.

Nature of allergy

I do not propose to discuss the various chemical and physical theories which have been advanced from time to time to explain the ultimate cause of the reactions of anaphylaxis and allergy. The recent theory of Lewis (1927) is generally accepted to explain most of the facts. Lewis believes that the interaction of antigen and antibody in susceptible tissues brings about a liberation of the loosely-combined histamine normally present in the tissues and it is this liberated histamine which causes the ultimate effect. Dale (1929) considers such a conception to fit all known facts. Dale suggests that, although it is only the sensitized cells that react, the histamine might be liberated from the reacting cells themselves or anaphylactic injury of the cells of a large organ such as the liver might liberate histamine into the general circulation in such quantities as to produce the effects generally.

* Hay fever is the term applied to paroxysmal sneezing, profuse watery discharge from the nose combined with nasal obstruction due to swelling of the mucosa, running from the eyes accompanied by severe itching of the mucous membrane of the nose, throat and palate occurring only at a certain season. The paroxysms are associated with the pollinating seasons of the trees, grasses or weeds to which the patient is hypersensitive. Outside this particular season he remains quite free from the effects.

† Paroxysmal rhinitis or spasmodic rhinorrhoea is the term applied to the condition in which the paroxysm of sneezing, nasal obstruction, running from the nose and eyes and itching, etc., are not confined to the pollinating season of any particular plant or plants but occur throughout the year whenever the patient comes in contact with the excitant. The excitants may include such substances as house or occupational dust, face and insect powders, animal emanations, powdered cereal grains, specific foods, drugs, incompletely broken up foods and toxins resulting from the bacterial action on such food, etc.

‡ It is to be clearly understood that all cases of asthma are not allergic in origin. Infection or disease of the respiratory tract (nose, throat, bronchi, bronchioles, etc.) and enlarged bronchial glands are responsible for a large number of cases of asthma amongst Indians.

§ Cyclical vomiting is a term applied to a malady amongst children characterized by lassitude, drowsiness, headache, fever, vomiting and marked muscular prostration. There is usually pain in the abdomen and constipation is generally present although in some cases there may be diarrhoea. The attacks begin at three or four years of age and continue at regular or irregular intervals up to 12 or 13 years of age.

Mechanism of allergy.—A number of attempts have been made by various investigators to demonstrate by means of passive transfer the presence of sensitizing antibodies in the blood of human allergies. The attempts to transfer the passive sensitiveness to guinea-pigs was attended with doubtful success. Prausnitz and Kustner thought of using the normal human skin, in place of the guinea-pig, for applying the method of passive transfer. They succeeded in passively and locally transferring fish-sensitiveness to the skin of an individual not sensitive to fish. Coca and Grove (1925) using this method demonstrated the passively-sensitizing property of the blood of all subjects of hay fever and asthma in whom the cutaneous reaction to the antigen was positive. These investigators studied the reacting properties of these sera and concluded that the sera contained a sensitizing body which was different in various respects from the anaphylactic antibody and gave it the name of 'atopic reagin'. These reagins have not yet been demonstrated in all the forms of human hypersensitiveness and Coca and others (1931) has offered a classification of hypersensitiveness* taking this and other points into consideration. He divides human hypersensitiveness into four forms:—atopy (strange disease) in which the reagins in the blood are present and the condition is subject strictly to heredity; hypersensitiveness of infection in which the reagins have not been found—the condition results from infection and is not specially subject to heredity; contact dermatitis in which the reagins have not been demonstrated—the condition develops after contact with the excitant and is not subject to atopic hereditary influence; and ordinary serum disease with possibly an ordinary form of drug idiosyncrasy in which the reagins have not been demonstrated,—the condition develops during the course of contact with foreign proteins and is not subject to atopic hereditary influence.

The mechanism of hypersensitiveness to non-antigenic substances, such as metals, drugs and active principles of poison ivy and primrose, etc., was obscure till the recent work of Landsteiner and his co-workers. As early as in 1912 Wolff-Eisner in explaining this hypersensitiveness to non-antigens suggested the combination of the non-antigenic substance with the individual's own proteins producing a blood foreign protein which acted as an antigen. This theory was based on the investigation of Obermyer and Pick who in 1906 showed that antigenic specificity of the protein could be modified by nitration, diazotization or halogenation of the protein. The assumption of Wolff-Eisner has been justified by the work of Landsteiner and his co-workers. Landsteiner and van der Scheer (1929) showed that the steric configuration, as

* He uses the term hypersensitiveness in its immunologic sense and excludes its general medical sense or the sense of increased reactivity.

well as the dominant chemical grouping, is an important factor in the specificity of the artificial antigens produced by linking a simple chemical substance of known structure to a protein. They prepared antigens by coupling the three isomeric tartaric acids (dextro, lævo and meso) with protein and the antisera prepared against these three artificial antigens which differed only in the steric configuration of the tartaric group exhibited only slight cross reactions. Goebel and Avery (1929) have further shown that when two simple carbohydrates, glucose and galactose,—which differ only in the steric configuration of a single carbon atom—are conjugated separately with the same protein, the antigens formed possess distinct specific characters. In this connection the observation of Whitfield (1921) is rather interesting as it tends to show the possibility of tissue protein to be so altered as to act as antigen. He cited cases of urticaria due to substances derived from a patient's own tissues. In his cases a blow on the skin or a fall produced a hæmatoma or ecchymosis without any breach of surface, nothing occurred for 10 days, at the end of which period there appeared a generalized, morbiliform, erythemato-urticarial eruption. The work of Manwaring and his co-workers in experimental anaphylaxis is very important in this respect. Manwaring, Hosepian, Enright and Porter (1925) produced evidence to show that canine anaphylaxis was due to chemical products explosively formed or liberated by the anaphylactic liver; these substances they called hepatic anaphylatoxin. Manwaring, Hosepian, O'Neill and Bing Moy (1925) produced further evidence of the existence of hepatic anaphylatoxins by cross-circulation, hepatic transplantation, and blood transfusion tests. Manwaring, Reeves, Bing Moy, Shumaker and Wright (1927) produced evidence to show that this hepatic anaphylatoxin must be regarded as a secondary antigen, presumably of protein nature and conceivably a denaturation product of the primary antigen explosively formed or liberated by the hypersensitive liver. Manwaring, Marino, McCleave and Boone (1927) produced further evidence to show that 'marked chemical alterations take place in specific antigens when injected into the animal body and that many of the essential immunologic adaptations are due to the resulting denaturation products (secondary antigens) rather than to the primary antigens originally injected'.

From what we have considered it is evident that in cases of allergy the offending substance or substances may be introduced into the body from outside or may be produced in the body itself. Thus, it may be inhaled as in hay fever, paroxysmal rhinitis, and pollen or dust asthma; it may be ingested as in food and drug allergy; it may be injected as in serum sickness; or it may be brought in contact with the skin or

mucous membranes as in dermatitis venenata and allergic conditions due to physical agents, such as heat, cold, light and mechanical irritation*. A small group of allergic manifestations may be ascribed directly to insect bites and stings. When produced in the body the offending substances may originate in an infective process within the body, or it may owe its origin to some pathological condition of the gut. Altered tissue protein itself may act as an antigen. The secondary antigens which are produced in the body by the primary antigen as shown by Manwaring and his co-workers in dogs also come into this category. It appears that infective foci, whether of teeth, tonsils, sinuses, or bronchi, liberate a substance which circulates and sensitizes various tissues and is capable of producing symptoms in the skin, respiratory and gastro-intestinal tracts, joints, etc. In the cases secondary to some pathological condition of the gut the substance or substances in question result from the bacterial action on the protein, or the proteins are broken down in some abnormal fashion and the altered protein gains access to the circulation. In India the allergy secondary to some pathological condition of the gut is more important than any other form of allergy. This is probably due to a lowering of the defence mechanism of the liver in the tropics caused by amœbic or some other form of hepatitis. That the detoxicating and the proteopexic function of the liver is defective in cases of allergy was first shown by Barber and Oriel (1928) who found important biochemical changes in the blood and urine of allergies. Dharmendra and Napier (1935) tested the liver function by various tests in 38 cases of asthma and detected defective liver function in 34 cases by the lævulose test or the adrenalin test or by both.

Allergic diathesis.—There must be certain factors that make some individuals respond in an abnormal fashion to substances that are quite harmless to ordinary people. In other words, the potential allergic differs from the normal individual in some way. This difference or predisposition has been designated by such words as 'exudative diathesis', 'allergic disposition', 'allergic constitution' and 'allergic diathesis'. This 'allergic diathesis' cannot be explained by a single factor but there are various factors to be taken into account. Different factors predominate in the different cases or different groups of cases. We will briefly consider the important predisposing factors:

(1) Heredity. Heredity plays a most important rôle in a majority of cases. Nothing definite is so far known as to the nature of inheritance. Many writers ascribe the transmission to a special nervous build. Eppinger

*Physical allergy is the term applied to allergic manifestations like urticaria, rhinitis, asthma, etc., when brought about specifically by a physical agent such as heat, cold, light and mechanical irritation acting on skin or mucous membrane.

and Hess consider the upsetting of balance between the vagal and the sympathetic constituents of the autonomic nervous system of primary importance. Endocrine dysfunction undoubtedly plays some part in bringing about the conditions and some writers believe glandular deficiencies to be directly or indirectly responsible for the transmission. It is difficult to say which of the two systems—the nervous or the endocrine—is of primary importance and influences the other since most of the glands are activated through the vago-sympathetic and on the other hand Burn (1933) found that the efficiency of the sympathetic nerve (that is, to say, the size of response elicited by a given impulse passing down a sympathetic nerve) depends upon the amount of adrenalin in circulation in the blood. The increased permeability of the endothelial system is another factor that can be transmitted. The question of a particular biochemical make-up being inherited looks an important one. Slight changes in the physico-chemical equilibrium of the body might be expected to lead to profound changes in its reaction to different circumstances.

(2) Since the excitants reach the tissues after absorption through the skin or the mucous membranes it seems reasonable to believe that abnormal permeability is one of the most important factors in bringing about protein hypersensitiveness by increasing the rate and amount of protein absorption. Schloss and Anderson (1922) produced evidence to show the enteral absorption of unaltered or slightly altered protein in marasmic infants with gastrointestinal disturbances. Anderson, Schloss and Myers (1925) showed that this enteral absorption took place in normal infants also but that the marasmic infants absorb much larger amounts and the absorption is continued over much larger periods than in the case of normal infants. Walzer (1927) has shown that in most persons unaltered food proteins enter the circulation in detectable amounts through the intestinal mucosa. It is quite conceivable that under altered conditions of permeability abnormal amounts of the unaltered food proteins enter the circulation. This has been actually shown to occur by Anderson, Schloss and Myers, as referred to above. O'Keefe (1927) is of opinion that there is definite and important relationship between the capillary circulation and allergic conditions, variations in capillary permeability affecting the amount and rate of protein absorption. Abnormal permeability may be an inherited factor or in the acquired cases it may be dependent on the excessive amount of histamine or allied poisons produced. Knott and Oriel (1930) have described in the sputa of asthmatics the presence of certain Gram-negative bacilli which during their growth within the small bronchial tubes give rise to histamine. Mellanby and Twort (1912) described the presence of

histamine in the intestinal wall and recovered a bacillus from the alimentary canal which converted histidine into histamine. Hanke and Koessler (1922 and 1924) found that histamine was a normal constituent of the large intestine of man and that this portion of the intestine normally contained micro-organisms that have the faculty of decarboxylating histidine into histamine and tyrosine into tyramine. It is quite conceivable that abnormal conditions in the intestines give rise to abnormal amounts of histamine and allied substances which alter the permeability. O'Keefe (1927) suggests that faulty digestion resulting in irritating intestinal contents might be expected to cause a change in the capillaries of the villi of the small intestine.

(3) The biochemical aspect. Important biochemical changes in the blood and urine are found during the attacks. Hurst suggested that in asthma there is some alteration in blood chemistry which renders an asthmatic subject liable to an attack of asthma from stimuli which in a normal person would produce no response. Barber and Oriel (1928) have found that the amino-acid content of the blood is raised during acute paroxysms of allergic manifestations and the whole blood chlorides seem to be markedly diminished. They pointed out the similarity of these blood findings to those of Haden and Orr in experimental intestinal obstruction. Haden and Orr concluded that the symptoms of toxæmia were due to proteoses absorbed through the damaged intestinal mucosa and that chloride was utilized to neutralize the toxic substances. In urine also, Barber and Oriel found important changes; immediately before and during the paroxysm there is a decrease in urinary output accompanied by a deposit of urates, an increase in free acidity and ammonia and a diminution in chloride excretion. During this period the urine gives a positive ether reaction for proteoses, to which they have attached a great importance. Following the paroxysm the quantity of the urine is increased and the urine becomes less acid or even alkaline and contains an excess of chlorides.

The calcium content of the serum and specially the calcium-potassium ratio has been widely investigated. It has been demonstrated that the effect of calcium and potassium on the cell was antagonistic, whereas calcium ions decrease nerve irritability potassium ions increase it. Some workers have reported low calcium contents of the blood in allergies but most investigators found no deviation from the normal figures.

Liver dysfunction.—The experimental work of Weil (1917), Weil and Eggleston (1917), and Manwaring (1921) demonstrated that the liver was the site of the anaphylactic reaction in dogs and that shock did not occur when the liver was thrown out of the circulation. It is very probable that liver dysfunction plays an

important part in the production of allergic symptoms in man, specially in allergy of intestinal origin. Osman (1929) suggested that in asthmatic children there is a diminution in glycogen reserve. O'Neill, Bing Moy and Manwaring (1925) found that glycogen disappears almost quantitatively from the canine liver during the first fifteen minutes of anaphylactic shock. McGuigan and Ross (1915) found a reduction of liver glycogen in peptone poisoning. It appears that the liver utilizes its glycogen to neutralize the toxins. The proteopexic function of the liver, *i.e.*, its power of fixing proteins and its derivatives, also appears to depend on an adequate supply of glycogen. In the absence of an adequate supply of glycogen in the liver, the unneutralized toxins and the proteins tend to pass the barrier of the liver and gain access to the general circulation. If this inadequate proteopexic function is combined with a- or hypochlorhydria, which makes the absorption of proteins capable of producing sensitization more likely, the chances of such a protein reaching the circulation are much increased. The detoxicating function of the liver is concerned in transforming products of protein digestion into urea and in rendering non-toxic the products of bacterial action on undigested protein. The biochemical findings in the blood and urine of allergies provide ample evidence of a basic toxic factor in these conditions. The chief source of this intoxication is the bowel and the inadequate detoxicating function of the liver allows the toxins to pass into the general circulation.

Disturbance in the acid-base equilibrium

Before leaving the question of biochemical make-up as a predisposing factor in the allergic diathesis reference must be made to the disturbance in the acid-base equilibrium towards the alkaline side which has been found in the allergies. The importance of this disturbed balance lies in the fact that it has been shown that changes towards the alkaline side increase sensitiveness in a sensitized tissue and a change towards the acid side reduces the sensitivity. Hemingway (1926) has shown that slight changes towards the alkaline side in the perfusing fluid brought about exaggerated responses in the sensitized tissue and that the addition of hydrochloric acid reduces the sensitiveness. McDowall and Thornton (1930) demonstrated the effect of slight changes in the H-ion concentration of the perfusing fluid in isolated bronchial preparations. A slight change towards the acid side causes a dilatation of the bronchiolar muscles and an opposite change towards the alkaline side brings about a constriction. In accordance with this view, efforts have been made to treat the allergic conditions by giving dilute acids or acid diets or by making the patient inhale carbon dioxide or hydrochloric acid gas in definite concentration. Intravenous

injections of hydrochloric acid have also been advocated.

Diagnosis of allergy.—(1) History. In cases of suspected allergy it is essential to go carefully into the history of the patient. Well-planned and careful enquiries enable us to elicit many points of great diagnostic value. In taking the history the following points should be noted keeping the significance of each at the back of one's mind. Any additional questions that are suggested by the nature of the case should also be put to the patient :

(a) Age of onset. Most allergic conditions commence early in life. It is important to find out the age at which the patient first noticed the onset of the symptoms.

(b) A history of inheritance is commonly found in the allergic cases. It is not only the particular manifestation of allergy, say asthma, from which the patient suffers that is to be looked for in the near blood relatives, but a history of allergy in general should be sought.

(c) Season of onset and the seasonal variations in the disease are of importance. This may give a clue to the offending flowers, foods, etc.

(d) There is a regular periodicity in the early stages of the allergic conditions. When they are severe and persist for several years they tend to become continuous. The history of dyspnoea having been a continuous feature from the very beginning excludes the possibilities of a case being one of asthma.

(e) Association of the disease with some particular place, food, animal, or profession may be elicited. Particular attention should be paid to the surroundings at home and work, such as the presence of factories and stables near at hand, the presence of or association with pets and poultry, horses, or cows, the presence of pillow-cases stuffed with chicken feathers, etc. In this connection enquiry into any alteration in the circumstances, surroundings, diet, etc., immediately preceding the initial attacks will be of much help. The details of the early attacks, before repeated attacks introduce the secondary factor of infection, are similarly very helpful. Any factor which in the patient's opinion may be responsible for his symptoms should also be noted down. As regards food, at times the provocative article or articles of diet can be named by the patient but in the majority of cases he has to be carefully dieted before any food can be incriminated.

(f) The past history of the patient should be looked into. Enquiries should be made if the patient has suffered from allergic conditions, *e.g.*, urticaria, angioneurotic oedema, hay fever, and food or drug hypersensitiveness. This might help in confirming or suggesting the diagnosis of the allergic nature of the ailment for which the patient is seeking advice. A history of having suffered badly from dysentery or digestive troubles is also very suggestive. In cases of asthma infections diseases of

the upper and lower respiratory tract should be enquired into.

(2) A total and differential blood count is made. Most allergic patients have a high blood eosinophilia.

(3) Protein skin tests are often of value in confirming the diagnosis when a careful history makes it possible to discover a specific substance responsible for the patient's symptoms. When no clue is afforded by the history at all in doing these tests we are to be guided by the fact that food is responsible for most cases of hypersensitiveness in infants and babies. As age advances, the inhalant factor becomes more and more important and in adults this is responsible for most of the cases, food hypersensitiveness being rather rare at this age. Amongst the inhalants the dust extracts made from the sweepings collected from sleeping or office rooms, factories, or any other place where the patient spends most of his time is an important one*.

These skin tests are based on the fact that those substances which, when inhaled, ingested, injected or taken into the body by any other means, are capable of producing allergic symptoms will also produce an urticarial weal when brought in contact with the lower layers of the skin.

The dermal tests are usually done on the forearm. The forearm is carefully cleansed with alcohol and scratches are made on it transverse to the long axis of the arm. The scratches are made only one-eighth of an inch in length and without drawing blood. One spare scratch is made to serve as a control. A drop of N/10 sodium hydroxide solution is put on each scratch and the substances to be tested are rubbed into them, one substance into one scratch, the control scratch receiving no substance. After about fifteen to twenty minutes the test fluid is wiped away and the results are read by comparing the site of each scratch with the control. A positive result is denoted by the appearance of an urticarial weal at the site of the scratch.

* The following are the most common inhalant and ingested excitants:—

Inhalants: Pollens; hairs of horse, cat, dog, cow, and goat; feathers of chicken, duck or goose; dust from sleeping and working rooms, factories, etc.; face and insect powders, and fungi and moulds.

Ingestants: Wheat, corn, rice, egg, milk, fish, meat, potato, etc.

It is to be noted in connection with the cereals that they can act as excitants on being inhaled, ingested or touched. It may be that a cereal can be well tolerated on ingestion but not on inhalation or contact or *vice versa*. There are people who can eat wheat flour with impunity but handling the flour gives rise to a severe type of dermatitis and its inhalation itching of the nasal mucous membrane, sneezing and watery discharge. Similarly there are persons who can handle wheat flour without any bad effect but who cannot stand it as a diet.

The intradermal method is more delicate than the dermal or scratch test but may give rise to severe reactions. An intradermal test is made by injecting a minute quantity, not more than 0.01 c.cm., of the test fluid of known dilution into the most superficial layers of the skin. A positive reaction is shown by the formation of a weal, and an area of surrounding erythema within fifteen minutes. A delayed reaction, consisting of an indurated area at the site of injection, specially in the case of bacterial antigens, may develop within 24 hours.

The protein test can be performed on the mucous membranes instead of on the skin. The ophthalmic reaction is used in cases of pollen allergy. A minute quantity of the pollen solution is introduced into the conjunctival sac. A positive reaction is indicated by itching and redness at the inner canthus, or the whole eye may become red or swollen. The nasal reaction is tested by blowing or spraying the pollen dust into the nose. When the excitant is a food, an oral reaction might be elicited by applying the protein to the lips and the mouth swelling and blistering may be seen in a positive reaction.

The material for doing the dermal test can be obtained in the form of paste in collapsible tubes from Messrs. Parke, Davis and Company. The supernatant fluid obtained by macerating a small amount of the substance in a small quantity of N/10 sodium hydroxide can also be used for the test.

Extracts for use of intradermal testing and for subsequent desensitization if a specific sensitivity is found to be present are made as follows:—

The material is washed with ether to remove fatty matter and is extracted with Evan's alkaline buffered solution. The extracting fluid is kept in concentrated form in two solutions*. For use, 100 c.cm. of each of these two solutions are mixed and made with distilled water to 1,000 c.cm.†. Toluol is used to prevent bacterial growth during the period of extraction. Toluol can be put as a thin layer on the top of the

Carbon dioxide is passed through it until phenolphthalein added to a sample of it remains colourless.

To avoid too great a dilution in extracting fruit and vegetable juice Coca suggests a stronger solution which he calls the preserving fluid one part of which is mixed with four parts of juice. The composition of this fluid is

NaCl	..	2.5 per cent
NaHCO ₃	..	1.25 "
Carbolic acid	..	2.0 "

fluid; with materials like flour it is better to mix toluol well with the dry substance before putting it in the extracting fluid. One to two days' extraction is quite sufficient. The extract is sterilized by passing through a Berkefeld type of filter. It should not be sterilized by boiling. The filtrate should be tested for sterility, both aerobically and anaerobically, before being used. The test should be performed with very weak dilutions to avoid undesirable effects. It is best to commence testing with a one-in-a-million dilution. One gramme of the substance is extracted with 100 c.cm. of the extracting fluid, this gives a 1/100 dilution. Further dilutions of 1/1,000, 1/10,000, 1/100,000 and 1/1,000,000 are made from it.

4. Prausnitz-Kustner reaction. When it is not advisable or practicable to do the usual skin tests, as in infants, nervous patients, patients with extensive and interfering skin lesions or with extremely dermatographic skin, or where the patient cannot attend for testing on account of distance or illness Prausnitz-Kustner reaction is tested. It is an indirect test which is performed with the patient's serum using the forearm of a healthy person. The test consists in injecting a small quantity of the serum from an allergic patient intradermally into a non-sensitive subject and then testing the sites of injection—which have been passively sensitized—with antigens to which the allergic patient is thought to be sensitive.

Five to ten cubic centimetres of the blood are withdrawn from the patient and the serum is separated with aseptic precautions. The forearm of the subject on whom the test is to be done is cleansed with alcohol and the serum of the donor is injected at two or more sites depending on the number of proteins to be tested. About 0.1 cubic centimetre of the serum is used for each injection and the site of injection is marked with ink or marking pencil. At least two to three hours should be allowed for the serum to be completely absorbed. Then each site may be tested locally for specific proteins by the scratch method, keeping one site as a control.

5. The best proof of a substance being responsible for the allergic symptoms of a patient is that the substance when brought in contact with the patient should precipitate an attack and its removal should relieve the symptoms. Whenever possible the positive results of dermal or intradermal tests should be checked with this criterion. All positive reactions may not necessarily be true specific reactions. The use of very concentrated solutions or large amounts of solutions in the intracutaneous test and many other causes give rise to false positive reactions.

6. In most cases of allergy a hypodermic injection of 0.3 to 0.5 c.c. of a 1/1,000 solution of adrenalin hydrochloride relieves the symptoms and this forms a good therapeutic test.

7. A careful examination of the stools is made. The allergic cases secondary to gut infection may show an *Entamoeba histolytica* infection or the presence of ova of various helminths. The McConkey neutral-red lactose agar plate may show various non-lactose-fermenting bacilli, causing post-dysenteric lesions. These findings are rather important from the treatment point of view.

8. A bacteriological and cultural examination of sputum is made in cases of respiratory allergy keeping the Gram-negative bacilli of Knott and Oriel specially in view.

9. A thorough search is made for any focus of sepsis which may be present in teeth, tonsils, nose, sinuses, appendix, etc.

Treatment of allergy

Immediate treatment.—Adrenalin hydrochloride is the most effective drug in relieving acute allergic symptoms. Usually 0.3 to 0.5 c.cm. of a 1 in 1,000 solution is given subcutaneously. The earlier the injection is given the smaller is the dose required. Graeser and Rowe (1935) have used adrenalin inhalation to cut short the attacks in asthma. A 1 in 100 solution of adrenalin chloride is used in a specially made nebuliser. Adrenalin is not effective when given by mouth. Adrenalin or ephedrine is used in the form of solution, spray, or ointment to relieve the local nasal symptoms in allergic rhinitis. A simple 2 to 3 per cent solution of ephedrine in distilled water may be applied locally to nose and eyes. Adequate local treatment should be given for the skin, joints, etc.

The proper treatment of the condition depends on the results of the investigation of the patient.

I. If the history, skin reactions, or elimination diets give a clue to the specific sensitization, then the treatment can be carried out on the following lines:

(i) Avoidance or removal of the specific causes. This is the ideal method of treatment but is practicable only in a minority of cases. Foods that disagree may be eliminated and when the allergy is due to some occupational factor the occupation, if possible, should be changed. Pets can be removed and cotton can be used to stuff the pillows in place of feathers. It is very difficult to avoid dust and pollen unless a dust-free chamber or a face mask is used; residence in the hills above 4,000 feet high excludes most air-borne allergens.

Van Leeuwen (1924, 1927 and 1931) was the first to introduce a dust-free chamber into which filtered air was pumped for the treatment of asthmatic patients. Since the time of his first experiments he has introduced a number of modifications to simplify the apparatus. He reports the results of treatment in 1,000 cases of asthma treated in allergen-free chambers; 70 per cent of the cases remained free, 20 per cent improved, and 10 per cent were refractory to the treatment. Leopold and Leopold (1925) had a special room built in which not only was the air dust and pollen free, but temperature and humidity were controlled as well. Cohen (1927) introduced a portable mechanical filter, operated by electricity, which produced and maintained pollen-free air. The cost of all these is very high and they cannot be available for the use of an average patient. To remove this difficulty Peshkin and Beck (1930) introduced a new and simplified air-filter consisting of a cabinet, rectangular in shape, 25 inches wide, 15 inches high and 9 inches deep, which contains the film screen, a pressure fan and an electric motor (1/30 horse power).

The whole unit is so comprised as to fit into a window frame and the current consumption is very low. Rappaport, Nelson and Welker (1932) undertook an experiment to determine the effect of air filtration in hay fever and pollen asthma. Their results indicate that air filtration is very effective in relieving the symptom of hay fever but that cases of pollen asthma respond very slowly to it.

(ii) In cases where avoidance is impracticable, for example where sensitization to multiple foods exists or where it is not possible to change the occupation, the treatment lies in trying to desensitize the patient against the allergen. In effecting desensitization two routes are available :

(a) When the allergen is a common food specific desensitization may be attempted by oral administration of minute but gradually increasing doses of the food in question. The treatment is commenced with very small amounts of food, it is given daily, and the doses are increased very slowly. Bray reports better results if small doses of the food are given with hydrochloric acid and pepsin mixture.

(b) In cases of allergy due to dust, pollen, or animal emanations desensitization is carried out by repeated subcutaneous injections of the sterile extract made from the substance. The extract is put up in 1/100, 1/1,000, 1/10,000, 1/100,000 and 1/1,000,000 dilutions. By means of intradermal tests the lowest dilution to which the patient reacts is found out, using 0.01 c.cm. of the different dilutions at a time and beginning with the lowest one. The skin is tested with 1/1,000,000 dilution first; if no reaction is obtained in 5 to 10 minutes the 1/100,000 dilution is tested; and so on till a positive reaction is obtained. Treatment is commenced with 0.1 c.cm. of the dilution next lower to the one that gives a positive test; for example, if the patient reacts with a dilution of 1/10,000, the treatment is commenced with 0.1 c.cm. of a 1/100,000 dilution. Subsequent injections are given at four to seven days' intervals and the dosage is gradually increased according to the patient's reactions. The course of injection occupies from two to three months.

(3) Along with avoiding the cause or desensitization, the co-existing infections or abnormalities of the respiratory or the gastro-intestinal tract should be adequately treated.

(4) Drugs. Calcium is reported to have a favourable effect on allergic conditions. The blood-calcium value in allergic conditions, though reported to be low by some workers, has been found to be normal by most of the investigators, so that calcium is used only empirically in the treatment of these conditions. If used, calcium should always be given with parathyroid as otherwise it is not assimilated, 10 grains of calcium lactate with 1/10th grain parathyroid may be given first thing in the morning and last thing at night.

Ephedrine may be given orally to control the symptoms during the period when desensitization is being carried on. Half a grain of ephedrine sulphate or hydrochloride given morning and evening is often sufficient. This drug may sometimes give rise to untoward effects and has then to be cut down or totally omitted. The most common disagreeable symptoms that follow the use of the drug are palpitation, nervousness, and tremors, nausea, vomiting, sleeplessness and headache.

Acids. The use of nitro-hydrochloric acid as an adjuvant treatment in cases of allergy has recently been much advocated, specially in view of the disturbance in the acid-base equilibrium to the alkaline side that has been shown to occur amongst allergies. Bray gives 30 to 90 minim doses of acid hydrochlor. dil. (B. P.) three times a day before or with meals in orange or lemon juice.

II. A thorough investigation will often fail to incriminate any particular food or animal emanation. In such cases the treatment is to be carried out on the following lines:

1. In allergy of alimentary origin the antigen absorbed may not be a whole food protein but the proteins may be broken down in an abnormal fashion and the altered proteins pass up to a liver whose proteopexic function is deficient and thus gain access to the general circulation. Or the toxins liberated by the action of bacteria on incompletely digested proteins may be the cause of the conditions. In treating such cases at least four factors have to be taken into account—

(i) Any infection found in the gut has to be carefully treated, *Entamoeba histolytica* infection by emetine or carbarsone, and hookworm infection by tetrachlorethylene, or an auto-vaccine may be used to confer immunity against the pathogenic organisms isolated from the stools.

Intestinal stasis, if present, should be adequately treated. Kaolin together with an intestinal lubricant such as liquid paraffin has been used to prevent absorption of toxic substances from the intestines in cases of rheumatoid arthritis.

(ii) Acid-pepsin mixture is of great benefit when there is evidence of hypochlorhydria. This is specially useful in children as cases of allergy of alimentary origin are most common at this age.

(iii) The patient should be kept on a more-or-less vegetarian diet, meat and fish should be kept down to a minimum.

(iv) The liver should be well looked after. Adam recommends acid and liver mixture after meals and a weekly blue pill. Glucose has been found to be useful in allergic conditions by Osman (1929) and Cameron (1929). Glucose therapy affords the simplest and most rapid method of increasing the glycogen content of the liver, upon an adequate supply of which its

proteopexic and antitoxic functions have been shown to depend. Glucose has been found to be specially effective in the case of children; in adults it is not so useful. Barber and Oriel (1928) recommend 2 to 4 ounces of glucose to be taken daily in divided doses. Glucose may be taken with meals or dissolved in water and flavoured with orange or lemon juice; it can be taken morning and evening on an empty stomach.

2. A thorough search should be made for any focus of infection in the teeth, tonsils, sinuses, bronchi, etc. Infective foci which can be removed should be dealt with surgically*. When the source of infection cannot be removed, an auto-vaccine prepared from the organisms isolated from the focus should be used. Special significance is attached to the vaccine prepared from the Gram-negative bacilli isolated from the sputum. Knott and Oriel (1930) found that these bacilli during their growth in the bronchi produce histamine. Oriel considers that local production of histamine in the bronchi in addition to causing a contraction of the plain muscles surrounding the bronchi would also tend to increase the permeability of the epithelium lining the bronchioles and facilitate the entrance of foreign proteins and possibly bacteria.

3. Non-specific protein therapy. The object of this form of treatment is to exhaust the sensitivity of the patient. Cecil (1935) thinks 'the most important function of the foreign protein reaction is the mobilization of immune bodies in the circulating blood'. Mackenzie and Fröhbauer (1927) have shown that in rabbits, which were previously injected with horse serum but in which the antibody to horse serum had disappeared, subsequent injections of chicken serum caused antibodies to horse serum to reappear. Petersen and others (1923) have shown that very small doses of peptone caused a lessened permeability of the endothelium. Hektoen (1935) believes that in the reaction to non-specific protein therapy important processes take place in the capillary walls and in the reticulo-endothelial system.

Protein therapy should not be used in the presence of active or quiescent pulmonary tuberculosis, cardiac or renal diseases, during pregnancy, in cases of exhaustion or in chronic alcoholics.

There are a number of substances which have been used for the purpose of non-specific therapy, e.g., peptone, serum peptone, proteoses, histamine, sulphur, autogenous blood, stock vaccines, auto-vaccines, tuberculin, gold salts, cobra venom and parasitic extracts.

4. The remarks about the use of calcium, ephedrine, and dilute hydrochloric acid as

adjuvants in the treatment given under the treatment of specific sensitivity apply here as well. In cases of allergy where an endocrine basis is suggested gland therapy may be of value. The suprarenals, thyroid and sex glands are most commonly involved. The desiccated glands may be given by mouth, but this procedure is only effective in the case of thyroid. Englebach (1932) has pointed out that only two of all the active principles of internal glands are effective when given by mouth. These two are thyroid and emmenin which are extracted from human placenta. In cases where hypoadrenia is apparent Bray gives ephedrine by mouth regularly. In patients in whom some definite relationship exists between their asthmatic attack and menstrual periods the attacks have been prevented by injections of corpus luteum. Injections of arsenical preparations such as soamin are used to tone up the endocrine system.

SUMMARY

Manifestations of allergy

Respiratory tract: hay fever, paroxysmal rhinitis and asthma.

Skin: urticaria, giant urticaria, dermatographia, dermatitis venenata, certain forms of eczemas and a variety of skin eruptions.

Gastro-intestinal tract: certain forms of gastritis, enteritis, mucous colitis and cyclical vomiting.

Nervous system: certain cases of migraine and epilepsy.

Joints: Paroxysmal hydrarthrosis and rheumatoid arthritis.

Urino-genital system: certain forms of enuresis in children.

Diagnosis of allergy

1. A history of inheritance is usually present.
2. The disease usually comes on early in life.
3. There may be an association of the disease with particular place, food, animals, pollens, etc.
4. There is a definite periodicity in the early stages of the allergic conditions.
5. There is usually high blood eosinophilia.
6. Protein skin tests may be positive to some excitants. Indirect skin test, i.e., the Prausnitz-Kustner reaction may be positive.
7. The best proof of a substance being responsible for the allergic symptoms of a patient is that the substance when brought in contact with the patient precipitates an attack and its removal relieves the symptoms.
8. A hypodermic injection of 0.3 to 0.5 c.cm. of a 1 in 1,000 solution of adrenalin chloride relieves the symptoms in most cases of allergy.

Treatment of allergy

The acute symptoms are relieved by a hypodermic injection of a 1 in 1,000 solution of adrenalin chloride. Inhalation of a 1 in 100 solution of adrenalin chloride in a special inhaler is useful to cut short the attacks of

* Operative measures on the nose, tonsils and sinuses, etc., are not always successful, because the conditions calling for the operation may not be the cause of allergy.

asthma. Ointments and sprays containing adrenalin and ephedrine are of value in the local treatment of the nose and a solution of ephedrine in distilled water is efficacious for local treatment of the allergic conditions of the eyes.

The treatment between the attacks—

1. If any clue is found to the specific antigen—

(a) avoid or remove the specific cause, or

(b) desensitize the patient with pollen, dust or epidermal extracts or with minute quantities of the food, etc., as the case may be, and

(c) along with avoiding the cause or desensitizing the patient any co-existing infections or abnormalities of the respiratory or gastrointestinal tract should be adequately treated. Any evident endocrine dysfunction should be attended to. Calcium, ephedrine and dilute hydrochloric acid can be used in suitable cases.

2. If no clue is found to the specific antigen.

(1) In cases of gut origin—

(a) any infection found in the gut should be carefully treated,

(b) an acid-pepsin mixture is of great benefit when there is an evidence of hypochlorhydria,

(c) the patient should be kept on a more-or-less vegetarian diet, and

(d) liver should be well looked after; 2 to 4 ounces of glucose taken daily in divided doses are very efficacious in children.

(2) A thorough search should be made for any focus of infection and, if present, it should be adequately treated surgically by means of auto-vaccines.

3. Non-specific desensitization may be tried with peptone, serum peptone, auto-hæmotherapy, milk, sulphur, tuberculin, T.A.B. vaccine, etc.

4. Endocrine therapy may be tried in suitable cases. Calcium, ephedrine and dilute hydrochloric acid may be used in some cases.

Medical News

ROYAL LONDON OPHTHALMIC HOSPITAL

('MOORFIELDS')

Medical School (University of London)

It is probable that during the time of the Coronation some old students of Moorfields, from overseas, will be in London. The Dean of the Medical School, Royal London Ophthalmic Hospital, is, therefore, preparing a short series of demonstrations that they may like to attend, and the following programme is being arranged:—

1. Exhibition of ophthalmoscopic conditions. Tuesday, 4th May, at 5-30 p.m.
2. Exhibition of slit-lamp cases. Thursday, 6th May, at 5-30 p.m.
3. Operation demonstrations: (a) Cataract.
(b) Glaucoma.
(c) Detachment.
(d) Squint.

- A selection of the above on the mornings of
- | | |
|--------------------------------|----------------------------------|
| | Monday, 3rd May. |
| | Wednesday, 5th May. |
| | Friday, 7th May. |
| 4. Orthoptics | Tuesday, 4th May, at 10 a.m. |
| 5. Pathological exhibitions .. | Wednesday, 5th May, at 5-30 p.m. |

The Dean informs us that they will be pleased to welcome any of their friends, and it would make arrangements easier if they would be so good as to send him notice of their intention to attend the course.

THE XIII ALL-INDIA MEDICAL CONFERENCE, 1936, KARACHI

We give below some of the more important resolutions passed at the conference:—

This conference is of opinion that there is an urgent and vital need of passing legislation in the shape of a *Pure Drug Act and Pharmacy Act* for British India, on the lines of that of United States of America, for the purpose of controlling the sale of drugs, as well as laying down the qualifications of the dispensers of drugs.

(a) This conference calls the attention of the medical profession, the government and municipalities to the urgent need of research in causes of malnutrition of the poor people of India and into the dietaries in various parts of India, and for the standardization of 'balanced diets' in different provinces, in accordance with the local dietetic customs of the people and the foods available during different seasons of the year.

(b) This conference desires to draw the attention of the government and the leaders of India to the fact that deficiency anæmias and diseases, tuberculosis, rickets, dental caries, infectious diseases, etc., spring from malnutrition. That the problem of prevention of diseases is partly a problem of the provision of sufficient and nutritious food for the people.

Whereas tuberculosis or white plague is insidiously making rapid inroads into populous cities in India and is responsible for high mortality incidence as shown by the vital statistics of the prominent municipal bodies in the country,

And whereas the disease is more or less endemic among the poorer section of the community and particularly among the children of school-going age whose parents and guardians can ill-afford to supply them with adequate amount of nourishing food like milk, fruits and eggs,

And whereas these children grow up poor in vitality with low resisting power which makes them more susceptible to tuberculous infection at this tender age,

This conference strongly urges upon various local bodies, district and local boards, educational institutions, government and private, carefully to collect the statistics of the disease in their respective jurisdictions, especially amongst children of school-going age, and inaugurate schemes of free milk supply to deserving children of poor parentage in humbler quarters of the cities, to provide them with adequate nutrition to fortify their constitution against the fell disease. The conference confidently hopes that such schemes, if earnestly pushed forward and assiduously carried out, will succeed in their object of building up healthy generation of manhood and womanhood.

This conference resolves that in view of the exhibition of obscene and indecent advertisement by means of newspapers, bills, and posters regarding medicines which are a nuisance and detrimental to the health of the public, particularly the young inexperienced girls and boys, the central and local governments and the local bodies be requested to take strong action to stop it.

Resolved that the government be requested to make the scheme for periodic health examination of school children compulsory and steps be taken for the preparation of a suitable scheme for the training of medical men for the purpose.

This conference requests the Government of India:—

(a) to amend the Indian Medical Degrees Act of 1916 in such a way as to make it unlawful for the unqualified persons to write any letters or words, with their names which may denote in a direct or indirect way the resemblance of these letters or words to be genuine or *bona fide* medical degrees, and

(b) to declare it an unlawful practice for such unqualified persons to place or write the designation of 'doctor' before their names.

This conference views with great concern the recent influx of a large number of doctors from foreign countries with which there does not exist any reciprocity and requests the government to take necessary measures to prevent such influx.

Resolved that in the opinion of this conference, registered medical practitioners should not have any connection with unaffiliated institutions for the teaching of the Western scientific system of medicine.

Resolved that this conference requests the government to initiate legislation to prevent any individual or corporate body to start or run any institution for the teaching of the Western scientific system of medicine, until such an individual or body satisfy some preliminary minimum requirements to be prescribed by the provincial medical councils.

Resolved that this conference views with alarm the rapid increase of 'open chemists' shops' owned and managed by the registered medical practitioners where consultation may be obtained free by all classes of people irrespective of their income or position in society.

Resolved further that this conference is of opinion that it should be declared unethical for registered medical practitioners to have any connection with an open shop where prescriptions other than his own or of other registered medical practitioners are served.

Resolved that this conference views with concern the growing tendency of the well-to-do and middle class public of utilizing free hospital facilities and thereby shutting out from the hospitals some of the poorer section of the public for whom such facilities are primarily intended and depriving the general practitioners of their legitimate income and experience.

Resolved that the Indian Medical Association be requested to take active and early steps to remedy the above state of affairs.

Resolved that this conference notes with regret the policy of some of the teaching institutions (official and non-official) in permitting their staff in charge of beds to hold positions in more than one teaching institution, leading to a state of affairs which is detrimental to the efficiency of the institutions.

Resolution:—

(a) Rural medical relief and sanitation being intimately connected with any scheme of village

reconstruction as fundamentally affecting the economic prosperity of a predominantly agricultural country like India, this conference is strongly of opinion that the Government of India and the provincial governments in the coming autonomous provinces should revise their public health policy in its essential aspects and give proper attention to it in their annual budgets.

(b) In provinces like Sind and the Punjab and others, where irrigation projects of immense importance and great magnitude have been launched and vast areas of land are under water for greater part of the year, this conference notes with regret that no adequate sanitary or drainage arrangements have been provided *pari passu* with the irrigation schemes. This deplorable state of affairs has resulted in unprecedented water-logging of such areas with consequent high malarial morbidity and mortality which has undermined the health of the countryside with considerable loss of man-power and economic ruination.

(c) While recording its sense of appreciation of the recognition, none too early, by the government of the paramount importance of rural reconstruction and the provision of the funds, however inadequate, in the central budget for the purpose, this conference is emphatically of opinion that such half-hearted measures will not touch even the fringe of the problem. It urges the governments, central as well as provincial, to make public health in the village reorganization the first charge on the state revenue; to set up sufficient rural dispensaries under qualified hands; to organize health and sanitation committees, child and maternity welfare centres and provide training facilities for *dais*; to undertake drainage and sanitary schemes in water-logged areas, and to push antimalarial measures with all the vigour and liberalize the quinine policy.

This conference is of opinion that the medical schools of the present day have outlived their usefulness and should either be brought in conformity with the minimum requirements laid down by the Indian Medical Council or be closed down without any further delay.

THE INDIAN HONOURS LIST

1ST FEBRUARY, 1937

THE following are the names of medical workers in the Indian Honours List of 1st February, 1937. We offer them our congratulations—

C.I.E.

Lieutenant-Colonel R. E. Flowerdew, I.M.S., Inspector-General of Prisons, Bengal.

G. C. Ramsay, Deputy Director of the Ross Institute of Tropical Hygiene and the London School of Hygiene and Tropical Medicine.

M.B.E.

M. D. R. David, Third Surgeon, General Hospital, and Police Surgeon, Rangoon.

Major H. C. Phillips, I.M.D., Superintendent of the Punjab Vaccine Institute, Lahore.

E. Duckworth, I.M.D., Manager, Medical Store Depot, Lahore Cantonment.

C.B.

Major-General A. W. M. Harvey, I.M.S., Deputy Director of Medical Services, Northern Command.

O.B.E.

Lieutenant-Colonel G. B. Hanna, I.M.S., Officer Commanding Indian Military Hospital, Quetta.

Kaiser-i-Hind Medal

(First Class)

Miss H. Betteridge, lately Superintending Missionary of the Zenana Bible and Medical Mission, Bombay.

Miss N. Hill, Organizing Secretary, Indian Red Cross Society and General Secretary, St. John Ambulance Association, Indian Council.

Lieutenant-Colonel G. M. Millar, I.M.S. (retired), Director, Medical Services, Jammu and Kashmir State.

Bar to the Kaiser-i-Hind Medal

(First Class)

Miss L. H. Hart, M.D., Medical Missionary, Madanapalle, Chittoor District, Madras.

Kaiser-i-Hind Medal

(Second Class)

Miss C. B. Allinson, Church Mission Zenana Hospital, Dera Ismail Khan, North-West Frontier Province.

Mrs. V. Inglis.

Mrs. E. F. Lethbridge, Lady Doctor at Kamaran, Quarantine Station, Aden.

Mrs. A. F. Morgan, Matron, Indian Hospital, Khargpur.

Miss M. O'Neill, Matron, Dai Khana, Ajmer-Merwara.

Miss N. Pathie, Assistant Surgeon, Dufferin Hospital, Rangoon.

Dr. J. A. M. Smith, Missionary, Church of Scotland Mission, Kalimpong, Bengal.

Kaiser-i-Hind Medal

(Third Class)

Miss V. North, Sister in charge of the Carmichael Hospital for Tropical Diseases, Bengal.

Khan Bahadur

Dr. S. A. H. Jafri, Bengal.

Rai Bahadur

Rai Sahib Dr. B. B. Mullick, Saran, Bihar.

Jemadar P. Bali, I.M.D., Sub-Assistant Surgeon, Cantonment General Hospital, Rawalpindi.

H. A. Shumshuddin Sahib Bahadur, Unani Doctor, Mayavaram, Tanjore District, Madras.

Rai Sahib

Dr. N. Pal, Patna Medical College Hospital, Patna.

Subedar K. C. Kapur, I.M.D., Fort Sandeman, Baluchistan.

Captain D. Shluwuliu, I.M.S., Bundi State, Rajputana.

MEDICAL COUNCIL OF INDIA

THE Seventh Session of the Medical Council of India was held on 12th February, 1937, in the Imperial Secretariat, New Delhi, 27 members being present, with Major-General Sir Cuthbert Sprawson in the chair.

The president, in his address, reviewed the activities of the council and on the eve of his retirement while wishing good-bye expressed satisfaction on its achievements.

A motion of condolence with the widow of the late Colonel H. H. Thorburn who represented the North-West Frontier Province Government on the council was adopted, all standing.

Colonel K. V. Kukday was re-elected vice-president of the council.

The following members were re-elected to the executive committee of the council:—

Dr. B. C. Ray.

Rai Bahadur Dr. B. N. Vyas.

Dr. Abraham S. Erulkar.

Lieutenant-Colonel S. L. Bhatia.

Rai Bahadur Dr. Maharaj Krishna Kapur.

The council considered the draft recommendations on professional education together with the observations of the universities thereon. With a few modifications they were adopted and it was decided that they should come into operation from the commencement of the academic year 1939.

The council accepted the regulations and rules of the Medical Council of India with some alterations and it was directed that they should come into force with effect from 1st April, 1937.

The council considered the question of the recognition of foreign medical degrees of repute when held by Indian nationals. The council was of opinion that Indian nationals who have obtained medical qualifications of repute in foreign countries should not be

proteopexic and antitoxic functions have been shown to depend. Glucose has been found to be specially effective in the case of children; in adults it is not so useful. Barber and Oriel (1928) recommend 2 to 4 ounces of glucose to be taken daily in divided doses. Glucose may be taken with meals or dissolved in water and flavoured with orange or lemon juice; it can be taken morning and evening on an empty stomach.

2. A thorough search should be made for any focus of infection in the teeth, tonsils, sinuses, bronchi, etc. Infective foci which can be removed should be dealt with surgically*. When the source of infection cannot be removed, an auto-vaccine prepared from the organisms isolated from the focus should be used. Special significance is attached to the vaccine prepared from the Gram-negative bacilli isolated from the sputum. Knott and Oriel (1930) found that these bacilli during their growth in the bronchi produce histamine. Oriel considers that local production of histamine in the bronchi in addition to causing a contraction of the plain muscles surrounding the bronchi would also tend to increase the permeability of the epithelium lining the bronchioles and facilitate the entrance of foreign proteins and possibly bacteria.

3. Non-specific protein therapy. The object of this form of treatment is to exhaust the sensitivity of the patient. Cecil (1935) thinks 'the most important function of the foreign protein reaction is the mobilization of immune bodies in the circulating blood'. Mackenzie and Fröhbauer (1927) have shown that in rabbits, which were previously injected with horse serum but in which the antibody to horse serum had disappeared, subsequent injections of chicken serum caused antibodies to horse serum to reappear. Petersen and others (1923) have shown that very small doses of peptone caused a lessened permeability of the endothelium. Hektoen (1935) believes that in the reaction to non-specific protein therapy important processes take place in the capillary walls and in the reticulo-endothelial system.

Protein therapy should not be used in the presence of active or quiescent pulmonary tuberculosis, cardiac or renal diseases, during pregnancy, in cases of exhaustion or in chronic alcoholics.

There are a number of substances which have been used for the purpose of non-specific therapy, e.g., peptone, serum peptone, proteoses, histamine, sulphur, autogenous blood, stock vaccines, auto-vaccines, tuberculin, gold salts, cobra venom and parasitic extracts.

4. The remarks about the use of calcium, ephedrine, and dilute hydrochloric acid as

adjuvants in the treatment given under the treatment of specific sensitivity apply here as well. In cases of allergy where an endocrine basis is suggested gland therapy may be of value. The suprarenals, thyroid and sex glands are most commonly involved. The desiccated glands may be given by mouth, but this procedure is only effective in the case of thyroid. Englebach (1932) has pointed out that only two of all the active principles of internal glands are effective when given by mouth. These two are thyroid and emmenin which are extracted from human placenta. In cases where hypoadrenia is apparent Bray gives ephedrine by mouth regularly. In patients in whom some definite relationship exists between their asthmatic attack and menstrual periods the attacks have been prevented by injections of corpus luteum. Injections of arsenical preparations such as soamin are used to tone up the endocrine system.

SUMMARY

Manifestations of allergy

Respiratory tract: hay fever, paroxysmal rhinitis and asthma.

Skin: urticaria, giant urticaria, dermatographia, dermatitis venenata, certain forms of eczemas and a variety of skin eruptions.

Gastro-intestinal tract: certain forms of gastritis, enteritis, mucous colitis and cyclical vomiting.

Nervous system: certain cases of migraine and epilepsy.

Joints: Paroxysmal hydrarthrosis and rheumatoid arthritis.

Urino-genital system: certain forms of enuresis in children.

Diagnosis of allergy

1. A history of inheritance is usually present.
2. The disease usually comes on early in life.
3. There may be an association of the disease with particular place, food, animals, pollens, etc.
4. There is a definite periodicity in the early stages of the allergic conditions.
5. There is usually high blood eosinophilia.
6. Protein skin tests may be positive to some excitants. Indirect skin test, i.e., the Prausnitz-Kustner reaction may be positive.
7. The best proof of a substance being responsible for the allergic symptoms of a patient is that the substance when brought in contact with the patient precipitates an attack and its removal relieves the symptoms.
8. A hypodermic injection of 0.3 to 0.5 c.cm. of a 1 in 1,000 solution of adrenalin chloride relieves the symptoms in most cases of allergy.

Treatment of allergy

The acute symptoms are relieved by a hypodermic injection of a 1 in 1,000 solution of adrenalin chloride. Inhalation of a 1 in 100 solution of adrenalin chloride in a special inhaler is useful to cut short the attacks of

* Operative measures on the nose, tonsils and sinuses, etc., are not always successful, because the conditions calling for the operation may not be the cause of allergy.

asthma. Ointments and sprays containing adrenalin and ephedrine are of value in the local treatment of the nose and a solution of ephedrine in distilled water is efficacious for local treatment of the allergic conditions of the eyes.

The treatment between the attacks—

1. If any clue is found to the specific antigen—

(a) avoid or remove the specific cause, or

(b) desensitize the patient with pollen, dust or epidermal extracts or with minute quantities of the food, etc., as the case may be, and

(c) along with avoiding the cause or desensitizing the patient any co-existing infections or abnormalities of the respiratory or gastrointestinal tract should be adequately treated. Any evident endocrine dysfunction should be attended to. Calcium, ephedrine and dilute hydrochloric acid can be used in suitable cases.

2. If no clue is found to the specific antigen.

(1) In cases of gut origin—

(a) any infection found in the gut should be carefully treated,

(b) an acid-pepsin mixture is of great benefit when there is an evidence of hypochlorhydria,

(c) the patient should be kept on a more-or-less vegetarian diet, and

(d) liver should be well looked after; 2 to 4 ounces of glucose taken daily in divided doses are very efficacious in children.

(2) A thorough search should be made for any focus of infection and, if present, it should be adequately treated surgically by means of auto-vaccines.

3. Non-specific desensitization may be tried with peptone, serum peptone, auto-hæmotherapy, milk, sulphur, tuberculin, T.A.B. vaccine, etc.

4. Endocrine therapy may be tried in suitable cases. Calcium, ephedrine and dilute hydrochloric acid may be used in some cases.

Medical News

ROYAL LONDON OPHTHALMIC HOSPITAL

('MOORFIELDS')

Medical School (University of London)

It is probable that during the time of the Coronation some old students of Moorfields, from overseas, will be in London. The Dean of the Medical School, Royal London Ophthalmic Hospital, is, therefore, preparing a short series of demonstrations that they may like to attend, and the following programme is being arranged:—

1. Exhibition of ophthalmoscopic conditions. Tuesday, 4th May, at 5-30 p.m.
2. Exhibition of slit-lamp cases. Thursday, 6th May, at 5-30 p.m.
3. Operation demonstrations: (a) Cataract.
(b) Glaucoma.
(c) Detachment.
(d) Squint.

A selection of the above on the mornings of

- | | |
|--------------------------------|----------------------------------|
| | Monday, 3rd May. |
| | Wednesday, 5th May. |
| | Friday, 7th May. |
| 4. Orthoptics | Tuesday, 4th May, at 10 a.m. |
| 5. Pathological exhibitions .. | Wednesday, 5th May, at 5-30 p.m. |

The Dean informs us that they will be pleased to welcome any of their friends, and it would make arrangements easier if they would be so good as to send him notice of their intention to attend the course.

THE XIII ALL-INDIA MEDICAL CONFERENCE, 1936, KARACHI

We give below some of the more important resolutions passed at the conference:—

This conference is of opinion that there is an urgent and vital need of passing legislation in the shape of a *Pure Drug Act and Pharmacy Act* for British India, on the lines of that of United States of America, for the purpose of controlling the sale of drugs, as well as laying down the qualifications of the dispensers of drugs.

(a) This conference calls the attention of the medical profession, the government and municipalities to the urgent need of research in causes of malnutrition of the poor people of India and into the dietaries in various parts of India, and for the standardization of 'balanced diets' in different provinces, in accordance with the local dietetic customs of the people and the foods available during different seasons of the year.

(b) This conference desires to draw the attention of the government and the leaders of India to the fact that deficiency anæmias and diseases, tuberculosis, rickets, dental caries, infectious diseases, etc., spring from malnutrition. That the problem of prevention of diseases is partly a problem of the provision of sufficient and nutritious food for the people.

Whereas tuberculosis or white plague is insidiously making rapid inroads into populous cities in India and is responsible for high mortality incidence as shown by the vital statistics of the prominent municipal bodies in the country,

And whereas the disease is more or less endemic among the poorer section of the community and particularly among the children of school-going age whose parents and guardians can ill-afford to supply them with adequate amount of nourishing food like milk, fruits and eggs,

And whereas these children grow up poor in vitality with low resisting power which makes them more susceptible to tuberculous infection at this tender age,

This conference strongly urges upon various local bodies, district and local boards, educational institutions, government and private, carefully to collect the statistics of the disease in their respective jurisdictions, especially amongst children of school-going age, and inaugurate schemes of free milk supply to deserving children of poor parentage in humbler quarters of the cities, to provide them with adequate nutrition to fortify their constitution against the fell disease. The conference confidently hopes that such schemes, if earnestly pushed forward and assiduously carried out, will succeed in their object of building up healthy generation of manhood and womanhood.

This conference resolves that in view of the exhibition of obscene and indecent advertisement by means of newspapers, bills, and posters regarding medicines which are a nuisance and detrimental to the health of the public, particularly the young inexperienced girls and boys, the central and local governments and the local bodies be requested to take strong action to stop it.

Resolved that the government be requested to make the scheme for periodic health examination of school children compulsory and steps be taken for the preparation of a suitable scheme for the training of medical men for the purpose.

This conference requests the Government of India:—

(a) to amend the Indian Medical Degrees Act of 1916 in such a way as to make it unlawful for the unqualified persons to write any letters or words, with their names which may denote in a direct or indirect way the resemblance of these letters or words to be genuine or *bona fide* medical degrees, and

(b) to declare it an unlawful practice for such unqualified persons to place or write the designation of 'doctor' before their names.

This conference views with great concern the recent influx of a large number of doctors from foreign countries with which there does not exist any reciprocity and requests the government to take necessary measures to prevent such influx.

Resolved that in the opinion of this conference, registered medical practitioners should not have any connection with unaffiliated institutions for the teaching of the Western scientific system of medicine.

Resolved that this conference requests the government to initiate legislation to prevent any individual or corporate body to start or run any institution for the teaching of the Western scientific system of medicine, until such an individual or body satisfy some preliminary minimum requirements to be prescribed by the provincial medical councils.

Resolved that this conference views with alarm the rapid increase of 'open chemists' shops' owned and managed by the registered medical practitioners where consultation may be obtained free by all classes of people irrespective of their income or position in society.

Resolved further that this conference is of opinion that it should be declared unethical for registered medical practitioners to have any connection with an open shop where prescriptions other than his own or of other registered medical practitioners are served.

Resolved that this conference views with concern the growing tendency of the well-to-do and middle class public of utilizing free hospital facilities and thereby shutting out from the hospitals some of the poorer section of the public for whom such facilities are primarily intended and depriving the general practitioners of their legitimate income and experience.

Resolved that the Indian Medical Association be requested to take active and early steps to remedy the above state of affairs.

Resolved that this conference notes with regret the policy of some of the teaching institutions (official and non-official) in permitting their staff in charge of beds to hold positions in more than one teaching institution, leading to a state of affairs which is detrimental to the efficiency of the institutions.

Resolution:—

(a) Rural medical relief and sanitation being intimately connected with any scheme of village

reconstruction as fundamentally affecting the economic prosperity of a predominantly agricultural country like India, this conference is strongly of opinion that the Government of India and the provincial governments in the coming autonomous provinces should revise their public health policy in its essential aspects and give proper attention to it in their annual budgets.

(b) In provinces like Sind and the Punjab and others, where irrigation projects of immense importance and great magnitude have been launched and vast areas of land are under water for greater part of the year, this conference notes with regret that no adequate sanitary or drainage arrangements have been provided *pari passu* with the irrigation schemes. This deplorable state of affairs has resulted in unprecedented water-logging of such areas with consequent high malarial morbidity and mortality which has undermined the health of the countryside with considerable loss of man-power and economic ruination.

(c) While recording its sense of appreciation of the recognition, none too early, by the government of the paramount importance of rural reconstruction and the provision of the funds, however inadequate, in the central budget for the purpose, this conference is emphatically of opinion that such half-hearted measures will not touch even the fringe of the problem. It urges the governments, central as well as provincial, to make public health in the village reorganization the first charge on the state revenue; to set up sufficient rural dispensaries under qualified hands; to organize health and sanitation committees, child and maternity welfare centres and provide training facilities for *daïs*; to undertake drainage and sanitary schemes in water-logged areas, and to push antimalarial measures with all the vigour and liberalize the quinine policy.

This conference is of opinion that the medical schools of the present day have outlived their usefulness and should either be brought in conformity with the minimum requirements laid down by the Indian Medical Council or be closed down without any further delay.

THE INDIAN HONOURS LIST

1ST FEBRUARY, 1937

The following are the names of medical workers in the Indian Honours List of 1st February, 1937. We offer them our congratulations—

C.I.E.

Lieutenant-Colonel R. E. Flowerdew, I.M.S., Inspector-General of Prisons, Bengal.

G. C. Ramsay, Deputy Director of the Ross Institute of Tropical Hygiene and the London School of Hygiene and Tropical Medicine.

M.B.E.

M. D. R. David, Third Surgeon, General Hospital, and Police Surgeon, Rangoon.

Major H. C. Phillips, I.M.D., Superintendent of the Punjab Vaccine Institute, Lahore.

E. Duckworth, I.M.D., Manager, Medical Store Depot, Lahore Cantonment.

C.B.

Major-General A. W. M. Harvey, I.M.S., Deputy Director of Medical Services, Northern Command.

O.B.E.

Lieutenant-Colonel G. B. Hanna, I.M.S., Officer Commanding Indian Military Hospital, Quetta.

Kaiser-i-Hind Medal

(First Class)

Miss H. Betteridge, lately Superintending Missionary of the Zenana Bible and Medical Mission, Bombay.

Miss N. Hill, Organizing Secretary, Indian Red Cross Society and General Secretary, St. John Ambulance Association, Indian Council.

Lieutenant-Colonel G. M. Millar, I.M.S. (retired), Director, Medical Services, Jammu and Kashmir State.

Bar to the Kaiser-i-Hind Medal

(First Class)

Miss L. H. Hart, M.D., Medical Missionary, Madanapalle, Chittoor District, Madras.

Kaiser-i-Hind Medal

(Second Class)

Miss C. B. Allinson, Church Mission Zenana Hospital, Dera Ismail Khan, North-West Frontier Province.

Mrs. V. Inglis.

Mrs. E. F. Lethbridge, Lady Doctor at Kamaran, Quarantine Station, Aden.

Mrs. A. F. Morgan, Matron, Indian Hospital, Khargpur.

Miss M. O'Neill, Matron, Dai Khana, Ajmer-Merwara.

Miss N. Pathie, Assistant Surgeon, Dufferin Hospital, Rangoon.

Dr. J. A. M. Smith, Missionary, Church of Scotland Mission, Kalimpong, Bengal.

Kaiser-i-Hind Medal

(Third Class)

Miss V. North, Sister in charge of the Carmichael Hospital for Tropical Diseases, Bengal.

Khan Bahadur

Dr. S. A. H. Jafri, Bengal.

Rai Bahadur

Rai Sahib Dr. B. B. Mullick, Saran, Bihar.

Jemadar P. Bali, I.M.D., Sub-Assistant Surgeon, Cantonment General Hospital, Rawalpindi.

H. A. Shumshuddin Sahib Bahadur, Unani Doctor, Mayavaram, Tanjore District, Madras.

Rai Sahib

Dr. N. Pal, Patna Medical College Hospital, Patna.

Subedar K. C. Kapur, I.M.D., Fort Sandeman, Baluchistan.

Captain D. Shluwuliu, I.M.S., Bundi State, Rajputana.

MEDICAL COUNCIL OF INDIA

The Seventh Session of the Medical Council of India was held on 12th February, 1937, in the Imperial Secretariat, New Delhi, 27 members being present, with Major-General Sir Cuthbert Sprawson in the chair.

The president, in his address, reviewed the activities of the council and on the eve of his retirement while wishing good-bye expressed satisfaction on its achievements.

A motion of condolence with the widow of the late Colonel H. H. Thorburn who represented the North-West Frontier Province Government on the council was adopted, all standing.

Colonel K. V. Kukday was re-elected vice-president of the council.

The following members were re-elected to the executive committee of the council:—

Dr. B. C. Ray.

Rai Bahadur Dr. B. N. Vyas.

Dr. Abraham S. Erulkar.

Lieutenant-Colonel S. L. Bhatia.

Rai Bahadur Dr. Maharaj Krishna Kapur.

The council considered the draft recommendations on professional education together with the observations of the universities thereon. With a few modifications they were adopted and it was decided that they should come into operation from the commencement of the academic year 1939.

The council accepted the regulations and rules of the Medical Council of India with some alterations and it was directed that they should come into force with effect from 1st April, 1937.

The council considered the question of the recognition of foreign medical degrees of repute when held by Indian nationals. The council was of opinion that Indian nationals who have obtained medical qualifications of repute in foreign countries should not be

granted recognition in India unless such foreign countries recognize the medical qualifications of this country on a basis of complete reciprocity.

The council noted the decision of the executive committee that the question of the recognition of the

medical qualifications of Andhra University should be postponed.

After transacting various routine business it was decided that the next meeting of the council be held on 25th August, 1937, in Simla.

Current Topics

The State of Nutrition of School Children in South India

PART I

By W. R. AYKROYD

and

K. RAJAGOPAL

(Abstracted from the *Indian Journal of Medical Research*, Vol. XXIV, No. 2, October, 1936, p. 419)

In spite of a growing realization that the diet of a large proportion of the population of India is unsatisfactory, few surveys of the incidence of malnutrition among school children, and others, have hitherto been carried out.

In the present investigation 1,918 children between the ages of 6 and 17 in three South Indian towns, Coonoor, Mettupalayam and Calicut, were weighed and measured. These children (with a further 85, making 2,003 in all) were examined to discover the frequency of xerophthalmia, 'angular stomatitis' and phrynoderma. In addition, the A. C. H. index of nutrition was applied to 1,145 of these children belonging to the age group 6 to 12. The association between the presence of the above symptoms and subnormal height and weight, and between the former and 'selection' by the A. C. H. index, has also been studied.

PHRYNODERMA

Dryness of the skin has often been noted in famine victims, and earlier writers on keratomalacia mention the presence of this symptom. Frazier and Hu described a follicular keratosis of the skin occurring in association with xerophthalmia and keratomalacia. They recorded that the eruption involved chiefly 'the exterior surfaces of the extremities, the trunk, and finally the posterior aspect of the neck..... Histologically, the pathologic process was primarily a hyperkeratinization of the lining epithelium of the hair follicles resulting in the obstruction of the follicles, particularly at the upper portion, by a dense mass of lamellated cornified cells'. Nicholls described this condition in Ceylon and gave it the name 'phrynoderma' (toad-skin) which has been adopted by other writers. The histopathology of the condition appears to resemble that of the classical *pityriasis rubra pilaris*.

In our investigation the outer surfaces of the arms were examined for phrynoderma. Only the presence of marked degrees of the condition was noted, i.e., cases which gave to the finger tips the sensation of passing over a rough surface. Mere dryness of the skin, which was found to be present in a very high percentage of children examined, was not recorded. There were naturally many border-line cases which were difficult to assign to the positive or negative groups. We tried, however, to keep the same standards throughout.

Phrynoderma is unquestionably due to diet deficiency, but evidence has been obtained that vitamin-A deficiency may not be the primary factor.

ANGULAR STOMATITIS

In the present investigation marked degrees of angular stomatitis were recorded. In many cases the interior of the mouth was examined also, and it is our experience that when fissures are present at the angles of the mouth the anterior part of the tongue will be found to be red and glazed. For rapid examination, however, 'angular stomatitis' is convenient. Nicholls, in carrying out examinations of school children in Ceylon, recorded the incidence of 'sore-mouth' differently. To quote his words: 'The standard adopted has been patches of superficial erosion of the mucous membrane of the tongue or lower lip, or its later stages, when the tongue becomes red or glazed. These patches are red and are in marked contrast to the unaffected parts of the tongue which show the whitish *duvet* of the slight normal fur. Some children with sore-mouths have excoriation and ulceration of the angles of the mouth. But when they have this condition without signs of erosion of the mucous membrane of the tongue or lower lip they are considered negative'.

XEROPHTHALMIA

Wright recorded the commonness of xerophthalmia and keratomalacia in the Madras Presidency. Xerophthalmia has been observed in some 26 per cent of children in famine camps in South India by Aykroyd and Krishnan. In the present investigation we noted all degrees of dryness of the conjunctiva, but in the final records we have included only cases showing 'Bitot's spots'. The yellowish foamy patches on the conjunctiva which are known by this name are easy to observe, and a convenient sign in routine examinations by non-ophthalmologists.

Clinical signs of deficiency disease in 'poor' and 'better class' schools (Coonoor).

		Number examined	Number showing one or more clinical signs	Percentage	Number showing phrynoderma	Percentage	Number showing angular stomatitis	Percentage	Number showing Bitot's spots	Percentage
'Poor' schools	Boys ..	158	50	31.6	26	16.5	25	15.8	10	6.3
	Girls ..	62	12	19.4	8	13.0	6	9.7	0	..
'Better class' schools.	Boys ..	621	65	10.5	41	6.6	43	7.0	6	1.0
	Girls ..	212	29	13.7	21	9.9	15	7.1	1	0.8

INCIDENCE OF CLINICAL SIGNS AT DIFFERENT ECONOMIC LEVELS

In the course of our examinations it became obvious that the children in the poorest schools in Coonoor were in a more wretched 'state of nutrition' than the children in the other schools. We have divided Coonoor schools into two groups, 'poor' and 'better class', and compared the incidence of signs of deficiency disease in each group. The 'poor' schools include two schools for the children of *dhobies* (washermen) and sweepers. 'Better class' is something of a euphemism, because many children of very poor parents attend these schools also. But at least it can be stated that poverty was less extreme in this group than in the other. The table below compares the incidence of clinical signs in the two types of schools. It was considerably higher in the 'poor' schools.

THE A. C. H. INDEX

The A. C. H. measurements of 1,145 children were determined. Column three of the following table shows

The A. C. H. index was applied to 1,145 children between 6 and 12. Of these 25.7 per cent were 'selected'. There is an association between 'selection' by the index and the presence of symptoms of deficiency disease, but the index 'misses' a considerable number of children showing such symptoms. It is suggested that the index needs adjustments to make it suitable for routine work in India.

The main result of our inquiry is to show that malnutrition due to diet deficiency is very prevalent among school children in three South Indian towns. It may be added that dietary deficiency was evidenced not only as described but also by the general appearance, posture and bearing of a large proportion of the children examined. The same state of affairs probably exists in towns and villages throughout the Madras Presidency. While it is only to be expected that children living on a diet largely composed of rice, with practically no milk and very few vegetables, should show obvious signs of malnutrition, it is useful to have some exact data on this point. Systematic surveys of

Selection by the A. C. H. index and its association with clinical signs of deficiency disease.

		Number A. C. H. index taken	Number selected	Per cent selected	Number showing clinical signs	Number selected of those show- ing clinical signs	Per cent selected	Number not show- ing clinical signs	Number selected of those not showing clinical signs	Per cent selected
Coonoor	Boys ..	314	102	32.5	90	52	57.8	224	50	22.3
	Girls ..	105	22	21.0	23	10	43.5	82	12	14.6
Mettupalayam	Boys ..	211	72	34.0	64	51	79.7	147	21	14.3
	Girls ..	45	14	31.1	6	4	66.7	39	10	25.6
Calicut	Boys ..	396	70	17.7	48	32	66.7	348	38	10.9
	Girls ..	74	14	18.9	4	1	25.0	70	13	18.6
All children ..		1,145	294	25.7	235	150	63.8	910	144	15.8

the percentage 'selected' of boys and girls in the various towns. In the sixth column of figures the percentage of cases showing clinical signs in the group who are 'selected' by the index is given, and in the ninth the percentage 'selected' of cases *not* showing clinical signs.

Of all children examined, 25.7 per cent were 'selected'. Taking both sexes together, a slightly higher percentage was 'selected' in Mettupalayam than in Coonoor (33.6 and 29.6 per cent respectively). In Calicut, the percentage of both sexes 'selected' was much smaller (17.8).

The percentages of all cases showing clinical signs who are 'selected' by the index was 63.8; the percentage 'selected' of those *not* showing signs was 15.8. There is thus an association between 'selection' by the index and the presence of clinical signs of deficiency disease.

SUMMARY

Average height and weight for the age group 6 to 15 (boys) was determined. The averages are compared graphically with those of other groups in Indian, Ceylonese, British and American boys. Indian children of a given height weigh very much less than British or American children of the same height.

In 14 per cent symptoms of food deficiency disease were present. 6.4 per cent showed phrynoderma, 9.2 per cent angular stomatitis, and 3.8 per cent Bitot's spots. The incidence of two former conditions in the children examined is compared with that recorded by other observers in groups elsewhere.

the state of nutrition of school children, following the lines of the present investigation, would throw great light on the problem of nutrition in India.

Stomatitis Due to Vitamin-B₂ Deficiency

By W. R. AYKROYD

and

B. G. KRISHNAN

(Abstracted from the *Indian Journal of Medical Research*, Vol. XXIV, No. 2, October, 1936, p. 411)

STOMATITIS with erosions of the lips and angles of the mouth occurring in ill-nourished groups has been described by a number of observers.

In a typical case white patches are visible at the angles of the mouth. The epithelium in this area has a sodden appearance, and the presence of fungus infection is suggested. White patches may extend inwards from the angles of the mouth to the mucous membrane of the cheek. Fissures are often present at the labial angles. Erosion of the mucous membrane of the tongue, particularly marked at the sides and the tip, is usually observed. Sometimes cracks are visible on the surface of the anterior part of the tongue. In severe cases much of the anterior part of the buccal cavity is red and eroded, and eating is painful. The posterior part of the cavity and the larynx appear not to be involved in the type of case usually encountered.

The general term 'sore-mouth' is often used by the laity to describe the condition.

We have found stomatitis of this type to be very common in children in South India, both in those attending day schools and those living in residential hostels. In the present paper the type of diet which leads to stomatitis is described, and evidence is produced to show that the condition is due to deficiency of one or more of the factors present in the vitamin-B₂ complex. During an investigation of diet in relation to 'state of nutrition' in children's boarding schools and hostels we found a boys' and a girls' hostel, within a short

cases 'sore-mouth' with erosion of the tongue was present.

The diets were composed largely of milled parboiled rice, other foods being present in small quantities. Judged by the usual standards both diets were deficient as regards almost all the food factors enumerated. The diet of the boys was the more deficient of the two, particularly as regards calcium. Diets of this type, in which rice predominates and the amount of protective foods included is small, are those usually found in association with stomatitis. Xerophthalmia and 'phrynoderma' were also observed among the children,

Typical appearance of 'angular stomatitis' in a girl aged 10.*

distance of each other and supported by the same mission, in which a high percentage of children was suffering from stomatitis. These hostels were within a few miles of Coonoor and an opportunity arose of trying different forms of dietary treatment for this condition.

STOMATITIS AND DIET IN THE HOSTELS

There were 32 pupils in the boys' hostel, and 35 in the girls'. All ages between 7 and 19 were represented, the majority of children being from 10 to 16. Of the boys 16 (50 per cent) and of the girls 25 (71 per cent) were found to be suffering from 'angular stomatitis'—fissures at the angles of the mouth. In the majority of these

the latter condition in a high percentage; we are not, however, concerned here with these conditions. The general state of nutrition of the children was visibly very poor.

The cost of food in the boys' and girls' hostels was about Rs. 2-3 and Rs. 2-9 per child per month, respectively. At this level of expenditure very little variation in diet is possible, and the diets described may be taken as typical of those consumed throughout the year.

* Reproduced with the permission of the Editor, *Indian Journal of Medical Research*.

TREATMENT OF STOMATITIS

The nine worst cases in the boys' hostel were chosen; all these showed glossitis in addition to fissures at the angles of the mouth. Five were given 0.5 oz. (14.0 g.) daily of cod-liver oil for three weeks. No improvement was observed. Simultaneously the other four cases were given 1 oz. daily of dried brewer's yeast (obtained from a local brewery). Improvement was visible in one week and within four weeks the white patches and erosion at the angles of the mouth, and the soreness of the tongue, had disappeared.

The five cases not improved by cod-liver oil were given daily 1 oz. of dried yeast autoclaved for five hours at 120°C. One other boy not previously treated was included in this group. Four cases were cured within four to five weeks. One boy left the hostel after four weeks' treatment with autoclaved yeast very much improved but still showing slight evidence of stomatitis. In the sixth case all signs of stomatitis did not disappear until after seven weeks' treatment. This boy complained of abdominal pain after taking yeast. We gained the impression that autoclaved yeast has a slightly less rapid action on 'sore-mouth' than unheated yeast.

During the period of treatment by unheated and autoclaved yeast all boys consumed the ordinary hostel diet and no changes were made in this diet. No improvement took place in cases receiving no diet supplements, so that the disappearance of stomatitis can not be attributed to a seasonal factor.

On the date that treatment was begun in the boys' hostel, the girls' diet was supplemented by 1.5 oz. (42 g.) of New Zealand dried skim milk daily. This was taken in liquid form, 8 oz. of water being added per oz. of milk powder to reconstitute liquid skim milk. Careful supervision ensured that each girl drank her ration of 12 oz. of liquid skim milk. All the girls were given milk.

Improvement in stomatitis was visible in a week, and within three to four weeks all cases were cured. The condition was possibly somewhat less severe among the girls than among the boys, although present in a larger percentage of the former. Among the girls there were no 'control' cases not receiving milk, but the rapid improvement which took place when milk was given left us in no doubt that milk was the operative factor. During the same period a number of boys with stomatitis in the neighbouring hostel, on a very similar diet without milk, showed no improvement. Subsequent laboratory investigation showed that the skim milk powder used was devoid of vitamin A.

Brief mention may be made here of the change which took place in the appearance and bearing of the children receiving skim milk and yeast. This was peculiarly striking among the girls receiving milk. It can perhaps best be described as an enhancement of *vitality*, very evident to the observer. Complexions improved and eyes brightened. A rapid increase in weight was observed. We propose to carry out further experiments on the effect of milk (whole or skim) as a supplement to the diet of South Indian children, and in particular to observe its effect on growth.

DISCUSSION

Landor and Pallister have recently described stomatitis occurring in gaols in Malaya, which was found to be curable by yeast and marmite, fresh or autoclaved, and also by fresh liver. In its more advanced stages stomatitis was associated with spastic paraplegia and dimness of vision. We have ourselves observed an outbreak of stomatitis in a gaol in South India, precisely similar to that recorded by Landor and Pallister, in which treatment by dried yeast and fresh cooked liver proved rapidly effective. In the same gaol an outbreak occurred a few years ago, in the course of which some patients developed spastic paraplegia. In these instances stomatitis was associated with the consumption of a deficient diet, largely composed of rice.

We have not observed any evidence of involvement of the central nervous system in children suffering from stomatitis.

Nothing suggesting pellagrous dermatitis was present in our cases and there were no signs of the mental changes characteristic of pellagra. Diarrhoea was absent. We have observed nothing resembling pellagra in the course of extensive field work in the Madras Presidency. At the same time the mouth condition described resembles that seen in the earlier stages of pellagra. 'In the first stage (of pellagra) we observe sodden fissured conditions at the angles of the mouth, a large indented tongue with central coating and bare glistening slides and tip, often with a shiny mucous coating these red borders and red buccal mucosa. The fungiform papillae appear as pinhead red elevations'. This is practically a description of the condition observed by us.

Possibly, therefore, we are dealing with a deficiency disease in which one of the symptoms of pellagra is present. The disease is curable by fresh unheated or autoclaved yeast, liver and skim milk. It follows that the B₂ group of vitamins is concerned. In our investigations vitamin-A deficiency was excluded by the fact that cod-liver oil produced no beneficial effect. There was no lack of vitamin B₁ in the diet of the hostels, since the staple cereal included was parboiled rice which retains vitamin B₁ after milling.

The observation that one of the most common food-deficiency diseases in the East is due to lack of one of the B₂ group of vitamins is of practical importance. One had been inclined to think that the greatest qualitative defect of the diets of the poorer classes in the East was their insufficient vitamin-A and carotene content. Cheap and convenient methods of supplying the deficient vitamin-B₂ factor must be the subject of further investigation. In children's hostels reconstituted skim milk or butter milk, costing about one-third the price of fresh whole milk, may be recommended as a valuable addition to the diet.

SUMMARY

1. Stomatitis was observed in two residential hostels for school children in which the diet supplied was deficient in various food factors.

2. The condition was found to be rapidly curable by daily doses of 1.0 oz. of dried yeast, unheated or autoclaved, or of 1.5 oz. of skim milk powder, cod-liver oil being without effect. It is assumed that it is due to deficiency of one or more of the factors in the vitamin-B₂ complex. The general condition of the children was greatly improved by the consumption of yeast and skim milk, particularly the latter.

3. The aetiology of the condition, in relation to pellagra and the various constituents of the vitamin-B₂ complex, is discussed.

Reviews

MODERN TREATMENT OF DISEASES OF THE RESPIRATORY SYSTEM.—By A. L. Punch, M.B., M.R.C.P., and F. A. Knott, M.D., M.R.C.P., D.P.H. 1936. J. and A. Churchill Limited, London. Pp. viii plus 295, with 96 plates and 31 text-figures. Price, 15s.

THIS is a book that will 'grow' on the reader whether he be a reviewer or just a seeker after up-to-date information. By this it is not meant that the first chapters are disappointing—on the contrary they are amongst the best, but as one goes through its pages, one realizes more and more that this book does supply

something that other textbooks have failed to supply. Emphasis is laid on treatment but of course diagnosis is not entirely ignored and the result is a very nicely-balanced presentation of the subject.

The book is a highly practical one, a fact which is very well brought out in the first few pages on the prevention and treatment of the common cold. The chapter on that extremely difficult subject asthma is also one that will appeal to the practitioner. A criticism that might be made is that the reader is not given much help for distinguishing the allergic type from the non-allergic, or perhaps one should say the 'less allergic'. A very timely warning is given against being misled, in the search for septic foci, by conditions which are themselves secondary to the allergic manifestations and which disappear completely if the patient can be relieved, even by palliative means, for a week or so.

A very useful feature is the excellent description given to technique of treatment procedures, such as the production of artificial pneumothorax, and important diagnostic methods, such as the typing of pneumococci; the immediate direct method is naturally the only one described.

There are many prescriptions given throughout the book and we are pleased to see that the authors have given the pharmacopoeial names in full; abbreviations that are quite justifiable in the written prescriptions are disfiguring to the printed page. The authors have provided a very good selection of skiagrams and the publishers have reproduced these both well and lavishly.

The student, practitioner, and specialist alike will find the book a very valuable addition to his library.

L. E. N.

TEXTBOOK OF MEDICINE.—By Various Authors. Edited by J. J. Conybeare, M.C., M.D. (Oxon.), F.R.C.P. Third Edition. 1936. E. and S. Livingstone, Edinburgh. Pp. xix plus 1027. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited (Publishers), Calcutta. Price, Rs. 14

THE object of this book is stated by the editor to be to provide '..... The essentials of medicine within as small a compass and as low a price as possible.....'. It is felt that the word essentials would be a better word in the title than 'textbook', for such an abbreviated and condensed publication is hardly worthy of the latter term.

The reviewer has studied the book particularly with reference to its possible use to students and practitioners in India and as a result has several criticisms to offer. In the section headed 'Skin granulomata' leishmaniasis, leprosy, yaws and mycetoma are mentioned but that very important condition granuloma inguinale is not included, and mycetoma is hardly a true granuloma.

The only treatment given for tapeworm is the old two days' starvation followed by a dose of filix mas and it is said if the head is not found treatment must be repeated. It has been known for a long time that many cases are cured without the head being found so it is better to wait for recurrence of passage of segments before subjecting the patient to a tedious and objectionable treatment a second time.

For ascaris, santonin is the only drug mentioned and 'with adults, doses up to 2 gr. may be taken safely'. This sentence would be considerably improved if the words 'and with probably little effect on the worms' were added to it.

Hookworm may be treated with thymol, oil of chenopodium and carbon tetrachloride. The much safer tetrachlorethylene is not mentioned, and the concluding sentence of this section is really dangerous for it says 'often prolonged treatment with all three drugs is

necessary before the disease is completely eliminated'. Not a word of caution is added about the necessary interval that must elapse between doses of these highly toxic drugs to avoid serious accidents, particularly in the case of carbon tetrachloride.

Many other instances can be found in the special sections of similar inadequate or misleading statements, but it is considered enough has been said to show the shortcomings of the book from the tropical practitioner's point of view.

One does not wish to appear hypercritical of what is a real attempt to provide a small and useful book. Many of the apparent mistakes and misinformation are no doubt caused by the necessity of rigid pruning and the utmost condensation possible, so as to keep the book within the prescribed limits.

Under the circumstances many essential points have to be omitted purely for want of space. In other words it is the reviewer's opinion that no matter how skilful the authors may be it is not possible to cover adequately all that is necessary to know about medicine in just over one thousand pages. This includes common skin diseases in under fifty pages. The number of small books purporting to be complete symposia of medicine but falling far short in their avowed object is nowadays very large, in the reviewer's opinion far too large, and at least as far as tropical practitioners are concerned, the book under review must be placed among the unwanted class, because even at the remarkably low price of 14 rupees it cannot be recommended for use in tropical practice.

KIDNEY PAIN: ITS CAUSATION AND TREATMENT.—By J. L. Jona, D.Sc. (Adel.), M.D. (Melb.), M.S. (Adel.), F.R.A.C.S., M.C.O.G. 1937. J. and A. Churchill, Limited, London. Pp. vii plus 84. Illustrated. Price, 7s. 6d.

THIS is a short but interesting and valuable publication.

It is an excellent example of how experimental methods may be combined with clinical observation and this is driven home to the reader by the citation of an actual case to illustrate each variety of pain causation discussed. The book is limited in scope and for that reason will probably not attract a great number of buyers among the practising part of the profession, who as a rule want more for their money. A great deal can be learnt from it, however, and it will well repay the study of general practitioners because kidney pain is a common and baffling condition and in this book much can be learnt about it; one of the most valuable teachings being how often kidney pain is caused not by disease of the kidney but by dysfunction brought about as a reflex from other diseased organs. Unfortunately the average practitioner will find difficulty in personally applying the diagnostic methods described because they need a good x-ray plant, special apparatus and considerable technical skill.

The book is copiously and well illustrated and there is a full bibliography. The printing, binding, paper, etc., are of the usual high standard one associates with the house of Churchill.

P. A. M.

THE OPERATIONS OF SURGERY.—By R. P. Rowlands, M.S. (Lond.), F.R.C.S. (Eng.), and Philip Turner, B.Sc., M.S. (Lond.), F.R.C.S. (Eng.). 1937. Eighth Edition. Volume II. The Abdomen. J. and A. Churchill Limited, London. Pp. ix plus 998, with 514 illustrations (four in colour). Price, 36s.

THE second volume of the eighth edition of Rowlands and Turner's *Operations of Surgery* has now been published. In the capable hands of these worthy editors this book has more than maintained its reputation. By the untimely death of R. P. Rowlands, British

surgery has indeed suffered a great loss, but, with the help of his colleague at Guy's Hospital, the whole book has been carefully revised, and a great deal has been rewritten.

As in the past, the present volume gives such detailed accounts of the operations of surgery as would be of real assistance to surgeons recently appointed to responsible positions, and to candidates for the higher examinations in surgery. The book has also succeeded in offering a fair criticism of newer methods that seem worthy of trial, especially those which stimulate thought and suggest the possibility of further researches. The new chapter on 'Some Recent Developments', at the end of the present volume, will be found both useful and interesting.

The chapters on abdominal surgery are adequate and up to date. Mr. W. H. Ogilvie has been in charge of several chapters, including those on the surgery of the spleen, pancreas, and the rectum. Gastric lavage and Ryle's tube have been mentioned in connection with persistent post-operative vomiting and acute dilatation of the stomach, but there is no mention of Wagensteen's suction apparatus. During recent years, the treatment of appendicitis has been fairly crystallized. The statement that 'when the cause of peritonitis is uncertain it is wise to use a right paramedian incision, otherwise the McBurney incision is the best', may be disputed. The first part of the statement might be generally acceptable, but, with regard to the latter, surgical opinion is bound to be divergent. In general, the former incision may be regarded as the incision of choice, in case of appendicitis, and in particular in the female subject.

Several chapters on urological surgery have been written by Mr. A. Ralph Thompson. Harris's suprapubic prostatectomy has been fully described. Suprapubic cystotomy has been recommended in the great majority of cases of ruptured urethra. In case of carcinoma, extirpation of the lymphatic glands has been recommended along with the amputation of the penis. There is no mention of Morson's views.

Gynaecological surgery has been dealt with by Dr. G. F. Gibberd. Wertheim's operation has been described in detail, but the modern revolt against such a mutilating and severe operation has not been emphasized. Vaginal hysterectomy has been rightly omitted. The section on thoracic surgery has been written by Mr. R. C. Brock.

These few criticisms are not meant to minimise or detract from the excellence of a standard compendium like the present volume. These will rather help to prove that this book is still indispensable to the practising surgeon and the post-graduate student. The printing, illustrations, and get-up are first rate. An adequate index is also appended.

P. N. R.

A TEXTBOOK OF PHYSIOLOGY.—By William H. Howell, Ph.D., M.D., Sc.D., LL.D. Thirteenth Edition. 1937. W. B. Saunders Company, Limited, Philadelphia and London. Pp. 1150, with 305 illustrations. Price, 30s.

THE reviewer feels it would be an impertinence on his part to recommend a book that has reached its thirteenth edition at the hands of its original author, who is one of the most renowned physiologists in the United States.

On account of the rapid advances in physiological science textbooks on the subject have to be revised at fairly short intervals to keep them abreast of the changes. In this revision it is important that the author should have a ripe experience so that he will know what to include of the new work, and what to ignore as likely to be of only temporary value, also certain theories that have held the floor perhaps for years but have outlived their usefulness must be discarded or

modified on account of recent work disproving them. This publication is fortunate in its author in this respect and the present edition maintains the high standard of its predecessors.

Although it is a heavy book it is well bound with a flexible back so that it need not be kept on a table when being read, because no matter how far it is opened there is no danger of the binding giving way.

P. A. M.

DISEASES OF THE VENOUS SYSTEM: THEIR ÆTIOLOGY AND TREATMENT BY INJECTION. SPA METHODS, THEIR INDICATIONS.—By P. K. Murphy, M.A., M.D., B.Ch., B.A.O. (T.C. Dub.). 1937. Henry Kimpton, London. Pp. vii plus 103. Price, 5s.

THIS small book is devoted to varicose veins and hæmorrhoids and their treatment, principally by injection.

It is a carelessly constructed book and the author has the habit of saying the same thing over and over again. If it had been carefully edited and the repetitions and redundancies deleted the subject-matter of real value would only occupy the space of an average-length paper in a medical journal.

On p. 26, line 2, there is an unfortunate error where 'If an obstruction is present.....' should obviously read 'If no obstruction is present.....' to make any sense of the paragraph. The want of care is also well exemplified where biniodide of mercury appears in the space of a few lines as Bi-iodure of Mercury, Bi-iodure de H, and biniodide of Hg. The first two renderings are apparently used because the prescription in which it is given is taken from the French.

In discussing spa treatment the author places Bagnoles-de-l'Orne in Normandy first and mentions two or three other French spas, and he ends the paragraph with a sentence 'A modified form of the "Bagnoles" treatment is, I believe, now being employed at British spas'. If he had followed up his belief and so given definite information as to which British spas could be recommended this section would have been of more use to the average British practitioner.

It is true the author does not claim it to be a book for teaching but rather as an expression of his views and experience together with a summary of current opinion. It would have had a better prospect of achieving its object if the facts had been marshalled in a more orderly manner.

HISTORICAL NOTES ON PSYCHIATRY. (EARLY TIMES—END OF SIXTEENTH CENTURY).—By J. R. Whitwell, M.B. 1936. H. K. Lewis and Company, Limited, London. Pp. xii plus 252. Price, 10s. 6d.

DR. WHITWELL'S book will be read by all interested in the history of the evolution of psychiatry with much interest, albeit the story does little credit to the intelligence of doctors in by-gone times, who clung so tenaciously to the view that mental disorder was either due to a visitation of God or the devil, or to some disturbance of bodily 'humours'. Only one voice of protest against these ignoble views is recorded, namely, that of Vincent de Paul (1576-1660), the wise and humane Frenchman, founder of numberless charitable organizations, among which was a mental hospital at St. Lazare. He was canonised by Pope Clement XII in 1737. An interesting feature of the book is a collection of chronological data of significance to the history of psychiatry. From this it appears that the first historical record of definite institutions for the mentally afflicted is to be found in the writings of Kuan Tzu who lived in the twelfth century B.C. No further record exists until A.D. 300 when a morotrophium (mental hospital) was built at Byzantium. In A.D. 491

a mental hospital was founded in Jerusalem. It is interesting to note that in the fifteenth century A.D. Spain led the world in providing accommodation for the insane. Indian readers will appreciate the number of references to eminent Indian medical sages, such as Charaka, Susruta and Vagbhata (we presume Dr. Whitwell means Banbhata). It would appear that the introduction of mental hospitals in India was the work of the East India Company, the first of which was founded early in the eighteenth century by Assistant Surgeon Conolly, a name later to become famous in the same department of therapeutics in the person of Dr. John Conolly (1794-1866), the humane superintendent of the lunatic asylum at Hanwell, who adopted the principles of Pinel. What records exist of the Madras mental hospital show that its founder was immensely ahead of his time in the ideas he entertained on the subject of psychotherapy.

DIAGNOSIS OF SOME DELUSIONAL INSANITY TYPES IN GENERAL PRACTICE: SCHIZOPHRENIA—DEMENTIA PRÆCOX—PARANOIDAL GROUPS: A SUMMARY OF IMPORTANT DIAGNOSTIC POINTS.—By E. Hopewell-Ash, M.D. (Lond.). 1936. Published by John Bale, Sons and Danielsson, Limited, London. Pp. 64. Price, 2s. 6d.

DR. HOPEWELL-ASH is a well-known author of a series of small yet valuable treatises on mental disorders, particularly in regard to their early symptoms. The latest of this series is extremely well written and should be of the greatest service for the type of medical man for whom it is intended, i.e., the general practitioner. It is rather lamentable that what Dr. Hopewell-Ash has to say about the inadequacy of instruction to medical students in psychiatry is as true to-day as it was thirty years ago. The diagnostic points dwelt on by Dr. Hopewell-Ash are illustrated by a selection of admirable case histories.

O. B-H.

A TEXTBOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY.—By Rai Bahadur J. P. Modi, L.R.C.P. & S. (Edin.), L.R.F.P.S. (Glasgow). Fifth Edition. 1936. Butterworth and Company (India), Limited, Calcutta. Pp. 823 plus cx with 1 coloured plate and 139 illustrations in the text. Price, Rs. 15

THE present edition of this book has, obviously, gone beyond the optimum in utility. An attempt has been made by a single author at a comprehensive treatise. Under all the old items additional facts and details have been amassed while recent advances have hardly been touched upon.

There is little or nothing said about the General Medical Council of India, the Provincial Medical Councils of India, and the employer's responsibility to the employee.

The section of bloodstains and blood groups is not only defective but also misleading. The serological test for determining the source of blood, as usually performed, is a ring test and not a turbidity test. Bernstein's theory of inheritance of blood groups deals with offspring of group A and group B, and also with offspring of group O and group AB. The combinations, group AB parent with group O child, and the group O parent with group AB child are not possible.

The myth of ptomaine is still with us. On the subject of toxicology a general remark on most books on the subject may be made here: *Cannabis Sativa* and *Strychnos Nux Vomica* are unusually well illustrated but no useful information is given on poisonous mushrooms. Nearly every medical student knows all about the former before commencing toxicology but

very few medical men know anything at all about the latter even after qualifying.

The treatment of snake-bite by Calmette's serum is out of date. A combined serum against cobra and viper has been manufactured at Kasauli for over 20 years. In 1934 this serum was refined and concentrated.

The list of books recommended at the end leaves out many recent publications.

Even if all the points raised above were attended to, there would still be left a want, felt by the practitioner and the student alike, which was so suitably supplied by the earlier editions of Dr. Modi's book.

When all is said and done, however, one would not like to be without a copy of the latest edition of a book by a pioneer in the field of forensic medicine in India. His personal experiences and observations, and his collection of cases no medical man with forensic responsibilities could afford to leave unread.

The paper, the printing and the binding are good. No printer's errors arrest attention.

ELEMENTARY PATHOLOGY: AN INTRODUCTION TO THE PROCESS OF DISEASE.—By Keith S. Thomson, M.R.C.S. 1936. H. K. Lewis and Company, Limited, London. Pp. vii plus 74, with 32 illustrations of which 3 are in colour. Price, 10s. 6d.

THIS is a somewhat curious little book which was intended to be a concise note-book for medical, dental and other students to give them a brief idea of the subject before they attend their lectures and practical classes. It is no doubt a novel and ingenious idea on which the author may be congratulated. Blank pages have been put in so that students may draw diagrams from what they actually see in the practical class. A short description of the various pathological processes has been appended.

The title of the book is most unfortunate and very misleading. To be more precise, it is nothing more than an improvised practical note-book. Although the author does not desire it, the book really tends to be an unusually short synopsis of elementary pathology. The illustrations, though well executed, are neither convincing nor appropriate, and, excepting a few, they have obviously been drawn from bad material. Mistakes have crept in even in the description of some of the figures. For instance, in fig. 23, 'colony of actinomycosis' is a bad expression. On the whole, the book cannot be commended to students of pathology in its present form. Considering its position as a practical note-book, the cost is too high. Perhaps the omission of the coloured plate of hypernephroma of the kidney and the substitution of a similar plate of organizing pericarditis and replacing the latter by a half-tone block of granulation tissue might help to reduce the cost of production very materially.

The book is however very attractive and for this, it owes its indebtedness to the excellent work by the publishers.

M. N. D.

WHAT IS WRONG WITH BRITISH DIET? BEING AN EXPOSITION OF THE FACTORS RESPONSIBLE FOR THE UNDERSIZED JAWS AND APPALLING PREVALENCE OF DENTAL DISEASE AMONG BRITISH PEOPLES.—By H. Campbell, M.D. 1936. William Heinemann (Medical Books) Limited, London. Pp. xiv plus 253. Illustrated. Price, 10s. 6d.

THE somewhat oratorical title along with the cover with which this book is endowed might tend somewhat to discourage a conscientious seeker after an ideal diet, but a perusal of its pages, which can be lightly read, justifies nevertheless serious attention. A certain

number of pages is devoted to the functions and nature of a complete diet from its nutritional point of view, namely, proteins, fats, vitamins, etc. A diet, however adequately equipped in its chemical make up, may yet be lacking in certain qualities necessary—to use a narrower term—for proper alimentation.

The author rightly stresses the importance of the physical texture of a diet. An adequate amount of roughage is, as is well known, necessary for the normal functioning of the alimentary canal, but the question of the toughness or softness of a diet on the normal development of the jaws and teeth has hitherto received scant attention; lack of proper mandibular exercise is held to be largely responsible for ill-formed jaws and overcrowding of teeth which one sees so often in the streets nowadays. Further, a food with a texture such as apples has a more favourable effect on oral and dental hygiene than the more pulaceous cooked foods. The author adduces a number of interesting facts and observations about malformed jaws but we feel from observation in India that the precise rôle of texture and nutritional value of the diet along with postnatal care has yet to be evaluated.

The book is well written and along with its illustrations should encourage many who are interested in diet on account of its slimming possibilities to realize that there may be other and more important æsthetic qualities to be hoped for from the art and science of nutrition.

MIND, MEDICINE AND METAPHYSICS: THE PHILOSOPHY OF A PHYSICIAN.—By William Brown, D.M. (Oxon.), D.Sc. (Lond.), F.R.C.P. 1936. Humphrey Milford, Oxford University Press, London. Pp. vii plus 294. Price, 7s. 6d. Obtainable from Oxford University Press, Bombay, India

THIS small book is a collection of addresses and essays by a well-known medical psychologist in which his views on various aspects of psychopathology and allied subjects are enunciated. Among other matters there is a dogmatic statement on the basis of psychology as to what the League of Nations should be and why it has failed in its objects up to the present.

It is a book that might be of interest to the practising general physician as a means of widening his knowledge in this special branch of medicine, but it is not sufficiently detailed to be of real value to one wishing to take up the subject of psychoanalysis as an aid in his daily practice.

SCALPEL AND SWORD.—By Sir James Elliott. 1936. Angus and Robertson Limited, Australia (89, Castlereagh Street, Sydney). Pp. 215. Price, 7s. 6d. (Obtainable in London from The Australian Book Company, 37, Great Russell Street, W.C.1)

UNDER the above title the author gives his personal experiences and reminiscences from the time of his arrival in New Zealand as a small boy until recent years.

These include description of the life of a medical student in Edinburgh, experiences in practice in New Zealand, and a certain amount of war service—in the South African war on a field hospital staff, and in the Great War in charge of a hospital ship. Interspersed throughout these personal anecdotes there are sketches of life in New Zealand and descriptions of much of the wonderful scenery in these islands.

It is a book that will be mainly of local interest but it will no doubt also appeal to that fairly large section of British readers who devour books on biography, travel and descriptions of countries other than their own.

P. A. M.

AGGRESSIVE MEDICINE.—By John Maberly, M.R.C.S. (Eng.), L.R.C.P. (Lond.). 1935. Baillière, Tindall and Cox, London. Pp. viii plus 232. Price, 10s. 6d.

THIS book with the attractive and startling title of *Aggressive Medicine* contains an account of the therapeutic uses and value of three drugs—iodized tincture of guaiacol, tincture guaiacol-chlor-iodide and tincture mansonia ovata, prepared by the British Drug Houses Limited, London. The conclusions finally reached by the author, who has used them on a number of his cases, are (1) that the iodized tincture of guaiacol is selective as regards serous membrane and fluids and is destructive to Gram-positive organisms, (2) that the tincture guaiacol-chlor-iodide is selective as regards blood and tissues other than of the serous type and is destructive to Gram-positive cocci, and (3) that tincture mansonia has specific action on Gram-negative diplococci such as *Neisseria catarrhalis*. He has used these drugs in a large variety of infectious diseases and has found them to be valuable 'internal antiseptics'. Meningitis, poliomyelitis, neuro-syphilis, pneumonia, bronchitis, pleurisy, synovitis, peritonitis, puerperal sepsis and other acute infections have all been cured by the use of these drugs. The dose of all of them is half to 1 dram twice a day. They act best when combined and bring about complete sterilization from infection. Brief histories of the cases treated by the author and results obtained are also given.

On reading the book one is apt to get the impression that the efficacy of these drugs is almost on a par with that of quinine in malaria and of arseno-benzene compounds in syphilis. It is no doubt true that guaiacol compounds have been extensively used in the treatment of some of the infectious diseases referred to by the author, but unfortunately the beneficial results obtained have not always been as marked as in the hands of the author. It would therefore be rather presumptuous to assume that these drugs are valuable specifics for the treatment of infectious diseases in which they have been employed by the author with success. Unless more extensive trials are carried out under controlled conditions the true place of these drugs in the therapeutic armamentarium of the physician cannot be assessed. The book as it stands is certainly an interesting one and is stimulating to thought.

K. V. K.

WOMEN EAST AND WEST—IMPRESSIONS OF A SEX EXPERT.—By M. Hirschfeld. 1935. William Heinemann (Medical Books) Limited, London. Pp. xix plus 321. Illustrated. Price, 12s. 6d.

MAGNUS HIRSCHFELD is certainly one of the great sexologists in the world and may be ranked along with recognized experts such as Havelock Ellis, Freud and others. When he writes a book on the very fascinating subject of women it is sure to attract universal attention and is sure to be read widely. But his book 'Women East and West' is a little disappointing because the title of it is a misnomer. There is very little in it about the women of the West and there is not very much about the women of the East. It is chiefly a record of important happenings and of impressions gained by the author during his tour of Japan, the Philippines, China, Dutch East Indies, India, Egypt and Palestine.

He tells us of the people he met, the lectures he delivered and the scenes he saw; here and there, as though to spice the narrative he makes a few observations regarding the women of these countries from the point of view of the sexologist and makes passing references to subjects such as marriage customs, sex life, prostitution and so on. Although there is nothing in the book that can be said to be of particular interest to the medical profession yet the lucid way in which he narrates the many events that took place and the

interpretations he gives to the many interesting observations that he made, makes the book very fascinating. It is therefore recommended as an excellent book for light reading during leisure hours, not particularly to the medical profession, but to the general public at large.

K. V. K.

OTHER BOOK RECEIVED

Mind and Vision: A Handbook for the Cure of Imperfect Sight without Glasses. By R. S. Agrawal, L.S.M.F. 1935. Published by the Author. Dr. Agrawal's Eye Institute, Delhi. Pp. viii plus 182. Illustrated. Price, Rs. 4.

Abstracts from Reports

REPORT ON THE ADMINISTRATION OF THE EXCISE DEPARTMENT IN THE PROVINCE OF BIHAR AND ORISSA FOR THE YEAR 1935-36

Ganja.—Nine licenses were issued for the cultivation of *ganja* during the year 1935-36, the same number as in the previous year. The total area under *ganja* cultivation during the year was 133 acres which produced 696 maunds of flat *ganja* and 206 maunds of the round variety and is expected to be sufficient to meet the demand of the provinces of Bihar and Orissa during the year 1936-37.

The total quantity of *ganja* issued on payment of duty was 36,117 seers against 35,757 seers in 1934-35. Consumption increased in nine districts and decreased in 12 but the fluctuation was not large in any district except in Purnea and Patna. The increase of 309 seers in Purnea was due to the slight improvement in the jute trade.

The Cooch Bihar system of supply.—*Ganja* continued to be exported to the Orissa State free of duty (other than Bonai, Gangpur, Kharsawan and Seraikella which took their supplies as usual from Sambalpur and Singhbhum on payment of duty) under what is known as the Cooch Bihar system of supply. The essential features of this system are that the State undertake to enforce complete prohibition of the cultivation of hemp plant, and also, the sale and possession within their territories of all *ganja* other than that obtained from the British warehouse, to co-operate with Government in all measures for the suppression of smuggling and illicit cultivation of *ganja* and to enforce the same rates of duty as are in force in the neighbouring British districts in return for which they are supplied with *ganja* duty free from *golas* in the British districts.

Bhang.—The contract for the exclusive privilege of collection, storage and wholesale supply of *bang* in the province continued with Babu Lachman Prasad Chaudhury. During the year he collected 543 maunds of *bang* in the district of Purnea and the whole quantity was stored in the central *gola* at Bhagalpur which had a previous balance of 84 maunds 35 seers 4 chittacks. The drug was supplied from the central *gola* to the warehouses of this province as well as to the provinces of Bengal and Assam. The quantity of *bang* issued under bond to wholesale dealers of this province was 261 maunds 20 seers against 181 maunds and 20 seers of the preceding year, while 225 maunds were exported under bond to Bengal against 250 maunds of the previous year. Twenty-eight seers of the drug were exported to the province of Assam on payment of duty in that province against 1 maund and 13 seers of the preceding year.

The total quantity of *bang* issued on payment of duty to retail vendors of the province during the year was 9,216 seers against 6,977 seers in the preceding year. Consumption increased in all districts except Shahabad and Darbhanga. Remarkable increases took place in the districts of Gaya (284 seers), Cuttack (552 seers), Puri (297 seers), Ranchi (125 seers), Palamau

(107 seers), Manbhum (352 seers) and Singhbhum (241 seers). Increase in these districts was chiefly due to reduction in the retail price of *bang* and on account of vigilance of the excise officers on the smugglers of non-duty-paid *bang*. The decrease in Shahabad and Darbhanga was nominal. The incidence of consumption per thousand of population was 3.9 chittacks against 2.9 chittacks in the preceding year.

Opium.—The total quantity of opium issued during the year to shops within the province was 20,826 seers against 20,086 seers in 1934-35. Consumption increased in 11 districts and decreased in 10. The increase was large in the districts of Balasore (306 seers), Puri (237 seers), Cuttack (186 seers) and Angul (36 seers) and was due to competition amongst vendors and to the slight improvement in the economic condition of the people in the Balasore district. The decrease in consumption was not marked in any district.

The practice of administering opium to children prevails to some extent in the districts of Cuttack, Balasore, Puri, Sambalpur, Hazaribagh, Ranchi and Palamau. Excise officers continued to explain the evil effects of the practice to the people found purchasing opium for children. Its evil effects were mentioned to students during lectures on hygiene by the school medical officer of Cuttack, and by the health staff of the Balasore District Board. In Puri, the officers of the District Board, the Municipality, the Education and the Public Health Departments did some propaganda work in this connection. Similar work was done in the district of Hazaribagh by the officers of the District Board and Education Department. It is reported that the practice is gradually on the decrease.

The habit of smoking prepared opium prevails to a certain extent in most of the districts but it is confined to towns and important centres of trade. There is no indication of the use of morphia as a substitute for opium as an intoxicant.

Cocaine.—Twenty-four persons were prosecuted during the year under report against 34 in the preceding year. The total quantity of cocaine seized weighed four ounces against three ounces in the preceding year. Cocaine traffic prevails at Bhagalpur, Patna and to some extent at Muzaffarpur. Particular care was taken to check the illicit traffic at Bhagalpur, which is most notorious in this respect, with the result that the activities of the smugglers remained under a strict vigilance and the number of the cocaine cases fell from 19 (1934-35) to 11 in the year under review.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ASSAM FOR THE YEAR 1935. BY LIEUT.-COLONEL T. D. MURISON, D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH

THE STATE OF THE PUBLIC HEALTH AND THE HISTORY OF CHIEF DISEASES

THE state of public health in the province was not satisfactory during the year under report. Deaths under all heads of mortality, with the exception of

'Injuries', were greater than in 1934. There was a severe outbreak of cholera in the Kamrup district. The largest increase in the number of deaths was from cholera, followed by an increase under fevers.

A total of 169,723 deaths was recorded during the year, of which 7,436 were from cholera, 529 from smallpox, 106,719 from fever, 10,947 from dysentery and diarrhoea, 7,022 from respiratory diseases, 2,051 from injuries and 35,019 from 'all other causes'. The death rate for the year 1935 was higher than the decennial rate by 2.12.

Cholera.—The total number of deaths reported from cholera during the year was 7,436 as compared with 1,904 in the previous year. The death rate per 1,000 of population was 0.94 against 0.24 in 1934, the decennial average being 0.89.

The districts which suffered most from cholera during the year were Kamrup, Darrang and Goalpara. Deaths from cholera were reported from 108 out of 147 registration circles and from 1,509 villages out of 28,333 in the province. The largest number of deaths (2,167) occurred in May followed by April (1,249) and June (1,080). The lowest mortality (134) was recorded in October. During the year under review, 102 deaths from cholera occurred in towns and 7,334 in rural areas.

A total of 333,534 persons was inoculated with cholera vaccine in 1935, excluding those inoculated in tea estates. A total of 1,020,481 doses of bacteriophage was issued during the year under review. Bacteriophage is being tried out in the Nowgong district and in the Habiganj subdivision of the Sylhet district. In these two areas cholera vaccine was not administered. As in past years, five mobile epidemic units, each consisting of three sub-assistant surgeons and six disinfectant carriers, were employed, viz, two in the Sylhet district and one in each of the districts of Goalpara, Kamrup and Nowgong. Their services are utilized throughout the province. The units in Nowgong and Habiganj are fully employed in the bacteriophage experiment, they are not therefore available for other duties. The establishment of epidemic units has been very fully justified and the provision of more such units is much overdue.

A total of 137 deaths from cholera was reported from tea estates during the year as compared with 104 deaths in the preceding year, the corresponding ratio per mille being 0.14 and 0.11 respectively.

EPIDEMIOLOGY

The number of deaths from cholera during the past eleven years was as follows:—

1925	..	6,233	1931	..	5,523
1926	..	10,275	1932	..	4,971
1927	..	15,392	1933	..	5,508
1928	..	6,915	1934	..	1,904
1929	..	7,765	1935	..	7,436
1930	..	6,332			

The increase in cholera mortality in 1935 was due to an increase of the disease in the districts of Sylhet, Goalpara, Kamrup and Darrang. The outbreak was most severe in the district of Kamrup. At first the outbreak was of a sporadic nature, but later it assumed an epidemic form partly owing to delay in reporting outbreaks and partly owing to the dryness of the weather which caused shortage and contamination of drinking water. All the available resources of the public health and medical departments were concentrated in combating this epidemic in the Kamrup district. The total number of deaths was 2,851. The

epidemic of cholera in the Goalpara district which broke out in the latter part of 1934 continued till March 1935. A total of 930 persons died in the Goalpara district during the year. In the Surma Valley only sporadic cases of cholera occurred throughout the whole year. In all these districts, particularly those in the Assam Valley, cholera was imported by emigrants from the Bengal districts both by land and water. The remaining districts remained practically free from cholera and only sporadic cases occurred.

Smallpox.—The total number of deaths from smallpox during the year 1935 was 529 against 206 in the preceding year, showing an increase of 323 deaths. The death rate was 0.07 per mille compared with 0.03 in 1934 and 0.33 the decennial average.

Plague.—No case of plague was reported from any district during the year under review.

Fevers.—The total number of deaths from fevers during the year 1935 was 106,719 against 101,779 in the preceding year, showing an increase of 4,940 over that of the previous year. The death rate per mille was 13.46 during 1935 as compared with 12.84 in 1934 and 11.87 during the last decennium.

'Fevers' accounted for 62.88 per cent of the total provincial mortality against 64.51 in the preceding year. The figures include deaths due to malaria, kala-azar and also deaths from various diseases having fever as their predominant symptom. It is therefore not possible to determine what percentage of the total deaths under this head is due to malaria. The largest number of deaths (11,823) was recorded in June and the smallest (5,883) in March. As in previous years, quinine and cinchona were distributed free to indigent malaria patients throughout the province.

Dysentery and diarrhoea.—The total number of deaths registered under 'Dysentery and Diarrhoea' was 10,947 during 1935 against 8,195 in 1934. The death rate per mille of population was 1.38 during the year under review as compared with 1.03 in 1934. The decennial average was 1.16.

Respiratory diseases.—The total mortality from these diseases during the year under review was 7,022 as compared with 6,440 in 1934. The corresponding death rates for the two years were 0.89 and 0.81 respectively. The quinquennial average was 0.73. The highest mortality (703) was recorded in November and the lowest (474) in February.

Epidemic dropsy.—An outbreak of epidemic dropsy was reported from Patharkandi in Sylhet district. Dr. R. B. Lal, Professor of Vital Statistics and Epidemiology, Calcutta, and the late Dr. P. Gupta, Assistant Director of Public Health, Surma Valley and Hill Division, carried out investigations. Outbreaks of epidemic dropsy were also reported from Silchar, Karimganj and Sylhet towns. No definite factor could be traced as being responsible for the causation of the outbreaks.

Yaws.—During the year under review a total of 4,201 cases of yaws was treated against 3,089 in the preceding year. The result of treatment has been found very satisfactory. Rate of relapse is very low, but this is very common amongst those patients who do not complete a full course of treatment. A total of 1,780 cases was treated in the Goalpara district, and in Kamrup 673. The disease which was generally prevalent in the low-lying hills and in the foot hills in this district amongst Mikirs, Lalungs, Kacharis, Garos and other hill people showed a marked decrease during the year under report. Exhaustive and thorough survey is being made to bring all foci of infections under control. In the Nowgong district a total of 592 cases was treated in the public health department dispensaries as compared with 431 in the preceding year. During the year under report four new centres were opened in this district. In the Garo Hills 180 cases of yaws were treated.

Kala-azar.—The number of deaths from kala-azar during the year 1935 was larger by 75 than that of 1934.

The number of patients treated was less by 2,298. The decrease is shared by all districts except Goalpara. The method of diagnosis and treatment of kala-azar continued to be the same as in previous years. Treatment is by means of intravenous injections of urea-stibamine. Owing to the increase in the price of neostibosan the treatment of kala-azar with this preparation was stopped in this province during the year under review. Special attention is given to intensive and detailed surveys in all districts in order to detect fresh cases and to bring them under treatment as early as possible.

Leprosy.—During the year under review, 4,926 lepers came under treatment in the leper asylums and other centres of treatment under the medical and public health departments. Three hundred and seventy-seven lepers were treated as inpatients in the Leper Asylums at Sylhet, Gauhati and Kohima and in the Leper Ward at Dhubri and the Leper Colony at Tura. One thousand two hundred and forty-four outpatients received treatment in the dispensaries under the Medical Department. A total of 2,305 lepers was treated in the Public Health Department dispensaries during 1935. The number of outdoor clinics for the treatment of leprosy during the year was 61 against 52 in 1934. The number of clinics in the medical department rose from 126 in 1934 to 138 in 1935. The Mission Leper Colony at Jorhat treated 110 lepers during the year. Nine sub-assistant surgeons of the public health department were trained locally during the year under report in the technique of leprosy treatment. Sub-assistant surgeons of this department undertake leprosy surveys in conjunction with kala-azar surveys. No special leprosy survey was undertaken during the year. The treatment although slow and tedious is becoming popular.

Malaria.—Malaria is prevalent throughout the province and almost constantly in epidemic form. A total of 733,408 cases of malaria was treated in all hospitals and dispensaries in the plains districts, viz., 664,920 cases were treated in dispensaries under the Medical Department and 68,488 cases were treated in Public Health Department dispensaries. Separate figures of mortality from malaria are not available, deaths from 'fevers' in 1935 amounted to 106,719 against 101,779 in the preceding year. A very large percentage of deaths under 'fever' is directly attributable to malarial fevers. Quinine-reinforced cinchona febrifuge was used as a general preventive and curative agent against the disease and was sold to the public at the cost price of annas 3.9 per treatment. Sales, on the whole, have been disappointing and in order to overcome this, Government has approved of the proposal to sell this preparation to the public in a smaller treatment form at the cost price of annas 2 per treatment. As in previous years the Government of Assam gave a grant of Rs. 25,000 to the Assam Medical Research Society for purposes of research. The society's activities are at present confined mainly to researches on malaria. These activities are summarized in the following note supplied by the Research Officer:—

'Many of the malaria surveys in hand in 1934 are now complete and, according to the findings, recommendations for the necessary anti-larval activities have been made'. Several surveys were, however, continued during the year in order to confirm findings previously made or to correlate findings with the researches being undertaken. Three new surveys, in an hyperendemic area, were undertaken to complete data necessary for the investigations in hand. The treatment centre at Doom-Dooma, for the evaluation of the use of plasmoquine in the field, was continued.

An eight weeks' course in malariology was held during July and August and twenty candidates passed the examination held at the end of the course. Entomological investigations included the identification of 152,075 anopheline larvæ, of 22,997 adult specimens and 9,348 adult anophelines dissected. Two species were found infected; 3,119 *A. minimus* and 1,046

A. culicifacies having sporozoite rates of 2.05 per cent and 0.38 per cent respectively, and the oöcyst rate of *A. minimus* was 3.21 per cent. *A. culicifacies* specimens found infected were from Lumding only. This species has not been previously reported as a carrier in Assam. Examinations of 16,972 blood slides, principally from hyperendemic areas, were made and in 6,899, or 40.66 per cent of these, malaria parasites were found. Data of 69,563 blood examinations have been completed from healthy, moderately endemic and hyperendemic areas in Assam. These data are being studied and a report is in course of preparation. Breeding experiments undertaken in the northernmost and coldest part of Assam have shown that under the coldest conditions present in the winter months, the adult of *A. minimus*, the principal vector of malaria, continues to emerge. With minimum temperatures averaging 54°F., the period required from the egg stage, through the larval and pupal stage to adult emergence averages 30 days. With increasing temperatures in April and May this developmental cycle from the egg to the adult emergence was reduced to 16 to 17 days and 12 to 13 days respectively. Other breeding experiments have shown that at least three batches of eggs can be fertilized by the spermatozoa retained in the spermatheca of *A. minimus* after primary matings, and that eggs of *A. minimus* are fertilized by the spermatozoa in the common oviduct during the act of oviposition.

Researches on malaria in Assam with special reference to cold weather and pre-monsoon anti-larval control have shown that the suitability of breeding conditions of *A. minimus*, the significant vector of malaria in Assam, falls into three separate groups which have been defined. The study of the malaria problem in two of these group areas shows that breeding of *A. minimus*, during the period January to mid-June, is the responsible factor for the increase in the malaria case incidence in moderately endemic areas and that, in the hyperendemic areas, breeding during this period is conducive to the rapid geometric progression in numbers of adults so that when rains breeding places are made available, breeding is transferred to these rains breeding places and continues until late November. The application of antilarval activities in the moderately endemic areas during the period early January to mid-June (i.e., until nature, by flushing, assumes control of stream breeding places of *A. minimus*) may be more economical than the present advocated period of anti-larval control (15th March to 15th November) as, during the former period, much smaller water areas would have to be controlled, with the habitat of the vector concentrated. Breeding would be stopped at its lowest point in the cold weather, and pre-monsoon months, preventing not only the subsequent geometric increase in the numbers of the vector when meteorological conditions become more favourable, but, in the absence of mature adults in April, May and June, would prevent the rise in malaria case incidence resulting from active transmission during this period. Malaria control, instituted on these lines and under expert supervision in three experimental centres (two moderately endemic and one hyperendemic), has shown, during one year, a parasite index reduction of approximately 50 per cent and spleen index reduction of approximately 25 per cent. Malaria control measures in these experimental control centres are being continued. Two other towns and also two groups of villages which have been surveyed are, during 1936-37, to be included in the experimental group. The bulk of the malariogenic areas in Assam, particularly in the case of villages, comes under the classification of 'moderately endemic'. Often a single small stream is the responsible breeding habitat: therefore, if our researches prove that we can control malaria by the application of antilarval measures to the small perennial streams during the cold weather and pre-monsoon months, it will become economically possible to protect from malaria the bulk of the villagers in Assam. A lump provision of Rs. 24,500 was made by Government for the purpose of carrying out anti-malaria measures in the province.

SEVENTY-FOURTH ANNUAL REPORT OF THE GOVERNMENT CINCHONA PLANTATIONS AND FACTORY IN BENGAL FOR THE YEAR 1935-36

THE market for quinine and cinchona has again remained remarkably steady throughout the year with the price showing little more than fractional variations due to differences in exchange. Demand is maintained, but except in India it falls far behind current supplies while the gulf which separates supply and potential demand is as wide as ever. The condition is chronic: it will probably not be righted until the fight against malaria is viewed throughout the world as a social service entitled to finance from Governments, from employers and generally from the enlightened section of the world's population. While education and a rising standard of living must have their effect in bringing malaria under control, nothing short of active State participation is ever likely to make much headway against the appalling suffering and loss of life that goes steadily on. In India, more than elsewhere, this truth may be said to be recognized and more than elsewhere it requires to be recognized, for we have the unenviable distinction of harbouring some of the world's worst malarial infection centres.

The difficulties that beset a wider and more efficacious Indian distribution of the drug are, however, not decreased at a time when constitutional changes are pending and when the future duty of growing and distributing quinine has still to be apportioned between the Central and Provincial Governments. It is, however, a happy sign that public opinion shows an increasing interest in this subject, for it is ultimately through the public conscience acting directly in public institutions or in the Government of the country that a solution of the quinine problem can be reached. It appears, however, from the trend of discussion in the legislature and in the press that the public are not so conversant with all aspects of the quinine problem as to make its interest practically effective. Its usual demand up till now has been for more and more and cheaper and cheaper quinine. It knows the remedy and it sees the ravages from malaria that go on. But there are practical difficulties in the way of all attempts to bring quinine at low rates to the great mass of India's sufferers. The general public cannot be expected to be aware of these and it may not be out of place here to refer to one, and what is probably the greatest, difficulty. The present high level of prices in cinchona products is essentially due to the difficulties of production. If the raw material were easy of production the manufacture of sufficient supplies of quinine would be easy enough, but cinchona as a plant is exacting in its demand and it is not everywhere or under any set of conditions that it can be successfully exploited. Costs of production are high, competition is restricted by reason of the climatic and soil requirements of cinchona and these combined explain high world prices.

The misfortune of these conditions was clearly recognized by the Health Committee of the League of Nations when they came to examine the question of the cheapening of quinine for the poorer malaria patient. The public demand for the lowering of quinine prices in India is obviously based on the fact that production costs here are lower than the level of world prices and Government are therefore urged repeatedly not to make a profit. The difficulty, however, is that the volume of production in India is quite insufficient to meet more than a fraction of the home demand giving the importer of quinine a virtual monopoly, and as long as this state continues so long will it be impossible for Government to reduce prices below market levels without the risk of supplies going astray into the hands of profiteers. And even if Government did take the risk their own supplies would serve but a small section of the population leaving the great bulk of national demand to be supplied by imported quinine at world prices. So far as the whole country is concerned, relief can only come from such an extension of local production as would effectively compete with

foreign quinine in meeting the total demand, and thus maintain prices at a level commensurate with the cost of production at home. It is fortunate that in India areas exist fairly suitable to the cinchona plant, and experience has shown that it can be cultivated here at costs which would allow of a cheapening of quinine for the masses.

When the public recognize this fact and finance is forthcoming there is no reason why a forward cinchona policy should not be adopted with every prospect of success. Experimental cultivation could be started under suitable conditions in different parts of the country, and all the accumulated experience of the existing cinchona organizations in India would be available to draw upon. But the success of such effort, if it is to be truly national, would seem to depend on a co-ordination of all the provincial efforts. Only certain provinces in India are fortunate in having suitable areas, and with the inauguration of provincial autonomy under the new constitution it would seem that the Central Government alone could bear the responsibility of such a national policy, so that the less fortunate provinces also may benefit. For under the present economic conditions it is not likely nor is it reasonable to ask that those provinces which can produce would make revenue sacrifices in the interest of others. This was probably one of the reasons why the Royal Commission on Agriculture stressed the importance of cinchona as a national programme. Since the Commission sat one difficulty has arisen. It lies in the fact that public health tends to be decentralized while cinchona seems to be linked with public health. But the production of quinine, as apart from its distribution, would scarcely seem to come within the scope of public health, and the public interest in prices seems to indicate that a co-ordinated and combined effort at production would be welcomed. What might be achieved by the pooling of resources is exemplified by the results in Bengal as shown in the present year's report.

Mungpoo.—The year's work has been progressive and returns show an increase in acreage of 81.29 acres and nearly rupees one lakh increase in block value. Weather conditions at the time of planting extensions were ideal and the plants put out have made good growth and refilling charges will not be very high next year. Some 19,000 plants of *ipecacuanha* were put out under covered lines during the year and the total standing crop is now 136,400 plants: a harvest of 380 lb. dry root for the year is recorded.

Munsong.—After filling in all vacancies in the previous year's plantings a total of 147.7 acres was put out in cinchona.

Experience has now been gained to give an opinion on present planting methods. Everything points to the fact that the longer the land is fallowed after a previous cinchona crop the better the results. The putting of old blocks for two years under green manures gives much better results than land filled in without the green crops, but, on the other hand, land which has been properly afforested with forest trees, or land which has not carried a cinchona crop, such as old *khet* land, gives still better results. Two small areas planted last year on Kashyem division in such land did so well that it was not worth while to trouble to fill in vacancies this year, though it was done due to plenty of plants being available. At the moment those two small areas are equal to any of the original plantings when they were of the same age. This type of land is now unfortunately not available. So it is a question of deciding if green manuring for the short period should continue or land be put under quick growing forest for 10 to 12 years before being used again. The writer is of opinion that if new areas can be opened up elsewhere to overcome this following period on Munsong the latter should be the future policy. The trees to be used to fallow the land can be specially selected for this purpose alone, in which case the period of fallowing could probably be less than that given above. Such species as *Erythrina* and *Albizia* to give humus, and *Alnus* to open up the soil, planted as a mixture

would be very suitable. To discontinue planting and fallow the land with forest trees would also likely be an advantage against the nursery disease. On the other hand, should conditions be such that Munsong must continue to replant as at present it seems desirable, and would pay from a cultural point of view, to extend the period under green manures for at least one year. This can be done as the best types of green manures for the purpose have, after considerable experimental work, been decided on and raised in sufficient quantity to supply the necessary seeds. The prevalence of disease on Munsong led to a policy of retaining in growth every tree that did not show definite signs of going off, but the decision to coppice such trees a second time will have to be reversed. They are usually so scattered as to make interplanting difficult while growth on the second coppice, if this does not kill the plant outright, is far behind growth after a first coppice. Experience shows that the double shock to the plant is beyond its powers of resistance. Root bark too is lost after the second operation. Healthy cinchona will stand it once but not twice, and we shall have to modify our cropping programme accordingly. In the coming year an increased bark harvest will have to come off Munsong because of the necessary removal of doubly coppiced areas that would lose in bark increment if left longer.

The nursery disease still awaits identification and, incidentally, a cure. During the year Miss Burt of the Hardinge Medical College, Delhi, and Mr. Kheshwalla of the Agricultural Research Institute, Pusa, visited Munsong in connection with it. These investigators are still working on the problem. The disease was prevalent in some nurseries more than others, Burmiak being the worst affected. Continual opening up of new nursery sites helps considerably, but lack of water and suitable sites, apart from the question of expense, places a limit on the extent to which this can be done in any one year. This and other practical methods against it continue year by year always in the hope of a remedy being found even though the mycologists are unable to give the disease a name.

The dry bark harvest was 871,795 lb., composed of Ledgeriana 797,848 lb., Officinalis 14,662 lb., Succirubra 10,601 lb. and Hybrids 48,648 lb. The bark came from dead and dying, thinnings, and coppicings from the refilled areas. In connection with the harvest 151.3 acres have been cut off including 9.9 acres which had to be written off against block 8, Burmiak on it being completely uprooted. The quantity of bark despatched from the plantation during the year was 886,493 lb. composed of Ledgeriana 812,780 lb., Officinalis 15,025 lb., Succirubra 12,437 lb. and Hybrids 45,251 lb. Of the total of 886,493 lb. despatched 200,000 lb. were sold to the Madras Government and 3,360 lb. to a Calcutta firm for experimental purposes, leaving a balance of 683,133 lb. as the quantity handed over to the factory.

Work at the factory continued during the year on lines indicated in the last annual report. There are no major developments to note but a number of quinine salts, not hitherto prepared by us, is now being supplied regularly to meet a small demand that exists and may grow in the future.

The total bark extracted was 1,361,941 lb., a reduction of 8 per cent on the previous year. Of this bark Munsong provided 61 per cent and Mungpoo 34 per cent, while the balance of 5 per cent came from the Government of India stocks of Burma and Java bark. Munsong bark contained an average of 4.37 per cent quinine sulphate, Mungpoo bark 3.75 per cent and India bark 4.1 per cent. The products obtained were as follows:—

Source of bark	Quinine sulphate	Cinchona febrifuge
Munsong	32,700	14,433
Mungpoo	15,691	7,584
Burma	1,580	494
Java	1,055	874
TOTAL	51,026	23,385

Besides the quinine sulphate obtained as such and shown above a further 3,157 lb. of it was contained in the cinchona febrifuge manufactured, bringing the total of quinine sulphate recovered from bark to 54,183 lb.

Of the Bengal quinine sulphate 29,144 lb. were purified to meet current needs, the balance being left in the crude state and stored in bins. Tablets were made from 12,791 lb., which shows an increase of 23 per cent on the previous year's figure. Other quinine salts manufactured made a total of 972 lb., nearly three times the quantity made in the previous year. This has meant a considerable strain on existing resources as the factory is not properly equipped for this type of work.

Opportunity was taken this year to make a more thorough overhaul of plant and machinery than usual. Laboratory work continued at high pressure. Apart from experimental work on current problems in connection with the process, the number of analyses made during the year of bark samples and intermediates was well over twelve hundred.

Correspondence

INFANTILE BILIARY CIRRHOSIS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I have just read an annotation, without seeing the original article, in the *Journal of Tropical Medicine and Hygiene* dated 15th December, 1936, in reference to a paper on infantile biliary cirrhosis by Dr. S. C. Lahiri in your June issue, 1936, wherein bacterial toxin is regarded as an important factor in the aetiology of this disease.

In the 'Transactions of the South Indian Branch of the British Medical Association', Vol. XVII (1923 or 1924), will be found a reference to a paper of mine in which it is suggested that the cause is a dietetic one resulting from the ingestion of curry stuffs and their irritant volatile oils by the pregnant mother. Such toxin is operative during intra-uterine life and continued at the breast. Many of these infants die during the first year of life.

In support of the above view is the experimental cirrhosis induced by feeding rabbits on hospital curry stuffs, which I carried out in Madras and at home. By feeding pregnant rabbits, a biliary cirrhosis is produced in the intrauterine foetal liver. Further feeding experiments on the ingredients of curry powder were conducted without detecting the essential toxic element, although it was found that rabbits fed on green chillies for three months never 'turned a hair', while controls on curry stuffs were dead in that time, all of them from cirrhosis of the liver.

As the detail of this experimental work is not reported in the transactions and some of it was carried out subsequent to that publication it is desired in this letter to draw the attention of those interested in India where biliary cirrhosis in the infant and the portal variety in the adult are prevalent diseases and possibly due to this error in diet. I have always regarded this as one of the pressing antenatal problems of the country.

Yours, etc.,

W. LEONARD FORSYTH, M.D., D.P.H.,

MAJOR, I.M.S. (Retd.),

Professor of Bacteriology.

UNIVERSITY OF CAIRO,

EGYPT,

18th January, 1937.

Service Notes

APPOINTMENTS AND TRANSFERS

The services of Lieutenant-Colonel D. H. Rai, M.C., are replaced at the disposal of the Government of the Punjab, with effect from the 15th January, 1937.

The services of Lieutenant-Colonel F. A. Barker, O.B.E., are replaced at the disposal of the Government of the Punjab, with effect from the date on which he assumes charge of his duties in the Jail Department.

The services of Major R. K. Misra are placed temporarily at the disposal of the Government of the United Provinces, with effect from the forenoon of the 30th December, 1936.

Major H. W. Mulligan, Officiating Assistant Director, Central Research Institute, Kasauli, is placed on foreign service under the Indian Research Fund Association to officiate as Director, Malaria Survey of India, with effect from the date on which he assumes charge of his duties.

In supersession of previous notification, in so far as it relates to Captain W. Scott, the services of that officer are placed permanently at the disposal of the Government of the Central Provinces, with effect from the 11th February, 1934, for confirmation in that province with effect from that date.

Captain E. A. O'Connor is temporarily employed to officiate as an Agency Surgeon, with effect from the forenoon of the 22nd October, 1936, and is posted to the North-West Frontier Province.

The services of Captain F. W. Allinson are placed temporarily at the disposal of the Government of Bengal, with effect from the afternoon of the 13th November, 1936.

The services of Captain M. S. Purvis are placed temporarily at the disposal of the Government of Burma, with effect from the forenoon of the 21st November, 1936.

The services of Captain S. T. Davies are placed temporarily at the disposal of the Government of Madras, with effect from the forenoon of the 2nd December, 1936.

Captain F. H. A. L. Davidson, on return from leave *ex-India*, is appointed as Civil Surgeon, Midnapore, *vice* Captain F. W. Allinson.

Captain E. H. Lossing, Second Resident Medical Officer, Presidency General Hospital, Calcutta, is appointed as First Resident Medical Officer of that institution, *vice* Dr. J. F. Colman.

Captain F. W. Allinson, Civil Surgeon, Midnapore, on relief, is appointed as Second Resident Medical Officer, Presidency General Hospital, Calcutta, *vice* Captain E. H. Lossing.

LEAVE

Major-General Sir Cuthbert Allan Sprawson, Kt., C.I.E., K.H.P., Director-General, Indian Medical Service, is granted leave, on average pay, from the 14th to the 28th February, 1937, preparatory to retirement.

Colonel N. M. Wilson, O.B.E., Inspector-General of Civil Hospitals, Central Provinces, is granted combined leave from the 17th February to the 15th September, 1937 (inclusive).

Colonel C. H. Reinhold, M.C., Inspector-General of Civil Hospitals, Punjab, is granted leave on average pay for 1 month and 16 days combined with leave on half-average pay for 4 months and 5 days, with effect from the 12th March, 1937, or date of availing.

Colonel C. E. Palmer, Inspector-General of Civil Hospitals and Prisons, Assam, is granted, preparatory to retirement, combined leave for 8 months, with effect from the afternoon of the 31st March, 1937.

Lieutenant-Colonel G. Covell, Officiating Director, Malaria Survey of India, on foreign service under the Indian Research Fund Association, is granted leave for 3 months and 23 days on average pay and for 4 months and 7 days on half-average pay, with effect from the 1st March, 1937, or subsequent date from which he may

avail himself of it. His services are replaced at the disposal of the Director-General, Indian Medical Service, with effect from the date on which he proceeds on leave.

Major J. E. Gray, Civil Surgeon, Nasik, is granted leave on average pay for 6 months combined with leave on half-average pay for 4 months, with effect from the 15th April, 1937, or the subsequent date of availing.

PROMOTIONS

Majors to be Lieutenant-Colonels

G. V. Ram Mohan. Dated 20th October, 1936.

H. Williamson, O.B.E. Dated 17th December, 1936.

N. M. P. Dotivala, M.C. Dated 23rd December, 1936.

Captain to be Major

W. Scott. Dated 3rd September, 1936.

Lieutenants (on probation) to be Captains (on probation)

Dated 1st November, 1936

V. D. Gordon.

B. deBurca.

D. R. Nicol.

J. Morgan.

G. R. C. Palmer. Dated 14th November, 1936, with seniority from 1st May, 1936.

A. C. Taylor. Dated 10th November, 1936, with seniority from 1st May, 1936.

J. Revans. Dated 10th November, 1936, with seniority from 1st May, 1936.

T. Somerville. Dated 10th November, 1936, with seniority from 1st May, 1936.

L. M. Kelly. Dated 10th November, 1936, with seniority from 29th June, 1936.

To be Lieutenants (on probation)

31st October, 1936, with seniority 31st October, 1935

Michael Carson Lyndon Smith.

William Laurie.

Benjamin Morrill Wheeler.

31st October, 1936

Arthur Henry Walter Mitchell.

Charles Henry Bliss.

James Heaton Cater.

James Duncan Munroe (Secd.).

Notes

A NEW HERNIA DIRECTOR

By LEONARD LEY, M.B., B.C. (Cantab.)

I HAVE noticed always that in dividing the neck of a hernial sac there is, even with the winged hernia director, considerable difficulty in preventing the hernia sac curling round.

It occurred to me that if the director had wider wings, and particularly if a deep slot was cut on each side of the grooved director so that the wings could slide down over the neck of the sac, the intestine would be completely isolated from the field and unable to slide up and over the director.

I wrote to Messrs. Down Brothers and they have carried out my ideas most meticulously.

I and my colleagues have since had several opportunities of testing the instrument and it has fulfilled all my anticipations.

The accompanying illustration will demonstrate the modifications I have mentioned above.

I am very grateful to Messrs. Down Brothers for the care they have taken in carrying out my suggestions.

IMPROVED NEEDLE HOLDER FOR PROSTATECTOMY

By J. COSBIE ROSS, ch.M. (Liverp.), F.R.C.S. (Eng.)

THE widespread performance and success of Harris' operation for suprapubic removal of the prostate necessitates a periodic review and possible alteration of the armamentarium. Two criticisms of the needle holder appear to be justified. In the first place the

fact that the shaft is straight causes the operator's hand to obscure the operative field and to make it difficult to place the catgut in the appointed slot, especially if the operation is complicated by an adipose abdominal wall or narrow pelvis. The second difficulty is that the actual insertion of the needle may induce bleeding. Harris states that 'in order to avoid hæmorrhage from the needle puncture, it is important that the needle should not have a terminal sharp cutting edge. The needle should be sharpened only at the actual point. It is made of rustless steel, and must be kept sharp'. I do not consider that this precaution goes far enough. The needle commonly supplied with the Harris needle holder is flattened from side to side, and although there is no cutting edge, a slit-like opening is produced which may induce hæmorrhage when the needle is inserted.

In an attempt to obviate these two difficulties I have designed a needle holder which has two main characteristics. The shaft is angled about half-way between the needle and the holder. This permits a clear view of the needle both at the moment of insertion and immediately afterwards, by keeping the operator's hand out of the line of vision. The angle involves the pilot being made with a series of joints similar to a chain so as to pass the bend. Secondly, a round-bodied needle is provided. In order to eliminate the occasional annoyance of the catgut slipping out of the slot before being drawn through the tissues, a lateral slot that renders this accident impossible is provided with the round-bodied needle.

I have now used this needle holder in many cases and have found it very satisfactory. The angled shaft permits a good view of the depth of the wound and the round-bodied needle causes no additional hæmorrhage. Finally, the needle appears to bite readily into relatively tough tissue.

The needle holder was made for me by Messrs. Down Brothers Limited, 22a, Cavendish Square, W.1, who also suggested the lateral suture holding slot.

CALCIUM GLUCONATE AND IRON

FOR use in conditions which arise from the deficiency of calcium and iron, 'Tabloid' calcium gluconate and iron (effervescent) has been issued by Burroughs Wellcome and Co. One dissolved in a tumblerful of water makes an effervescent draught containing 20 grains of calcium gluconate and three grains of iron and ammonium citrate.

The product meets the physiological demand for calcium and iron in adults and children where a deficiency in the dietary supply is suspected, but where no actual

clinical manifestations have been observed. Another suggested use of calcium gluconate and iron is during pregnancy and lactation to reinforce the dietary calcium and iron in order to cope with the demands for these elements by the developing fœtus or infant. It can be given with advantage over a long period to ensure an adequate supply of calcium for fœtal bone formation, and to replace the abnormal loss of iron during the pregnancy.

The dosage of 'Tabloid' calcium gluconate and iron in pre-natal cases is one product twice daily for a month then after the lapse of another month the treatment is resumed. An alternative method is to give one product daily over a period of several months. Where there is a marked deficiency of lime in the water

of some districts, larger doses can be given with benefit. The dose for normal use is one or two products daily in a tumblerful of water.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

TUBERCULOSIS IN INFANTS AND CHILDREN

By A. C. UKIL, M.B., M.S.P.E. (Paris), F.S.M.F., F.N.I.
(From the Tuberculosis Inquiry, I. R. F. A., All-India
Institute of Hygiene and the Chest Department,
Medical College Hospitals, Calcutta)

VERY little is known regarding tuberculous infection and disease in infancy and childhood

It is known that 15 per cent of the total deaths from tuberculosis in most European countries account for the initial peak of mortality from tuberculosis which has not yet been recorded in any municipal or non-municipal area in India. From the already increasingly high incidence and mortality rate from tuberculosis, especially in the urban and industrial areas, of this country and from the sanitary condition and hygienic habits of the people, one would expect a high mortality from tuberculosis in the earlier years. It has been previously noted by us that familial contagion is very frequent in India, a history

Fig. 1.—Mortality curve of tuberculosis in Calcutta.

Fig. 2.—Total tuberculosis death rates at age periods in England and Wales (1912-14 and 1923).

in India. Tuberculosis is now already recognized as the most important major cause of morbidity and mortality in India, probably only next to that of malaria (Russell, 1935).

of contact having been obtained in 40.2 per cent of x-ray-diagnosed cases (Ukil, 1933). We do not yet know very well what fraction of the notoriously high infantile mortality in India is

really due to tuberculosis, especially in tuberculous homes.

In an investigation to find out the position, we can get an idea from tuberculin surveys among infants and children among the average population, in tuberculous and non-tuberculous homes, from autopsy evidence and from hospital cases. Let us now see what evidence we can adduce from each.

Tuberculin survey among 1,656 apparently normal children in rural, semi-rural and urban areas

Age	Total number of cases tested	Percentage of positive reaction
0-5 years ..	236	11.4
5-10 " ..	813	30.1
10-15 " ..	507	33.3

These rates by the von Pirquet test are undoubtedly lower than in highly industrialized and urbanized Western countries, but this probably represents the correct Indian position. The average tuberculin incidence at all ages obtained by us in an earlier investigation (Ukil, 1928) was found to be 45.9 per cent and the evidence obtained from the bodies of persons dying of accidents or murder autopsied at the Calcutta police morgue has been found to be 47.8 per cent. When we analyse the autopsy evidence among only 23 children between 0-15 years, the figures are found to be slightly higher, as will appear from the table below:—

Age	Number of cases examined	Evidence of tuberculosis, per cent	Tubercle bacilli demonstrated by culture, animal inoculation and histological examination, per cent
0-5 years	15	33.3	20.0
5-15 "	8	37.5	37.5

The incidence, however, changes quickly in presence of a source of infection in the home, those having an intimate and recent contact showing a higher incidence than those having distant and remote contact (Ukil, 1930).

In one of our recent studies (unpublished) among 342 children from 0-15 years in tuberculous homes, the average incidence of positive tuberculin reaction by the Mantoux test was found to be 75.7 per cent. Among children between 0-5 years, it was found to be 70 per cent. These figures are a little higher than what Dow and Lloyd (1930) obtained in England some years ago. The comparative position among the contact and non-contact children as well as the

sources of contagion in our series are shown graphically below:—

Fig. 3.

Fig. 4.

Evidence of tuberculous disease in hospital cases

The following table shows the number of cases confirmed by tuberculin and x-rays at the chest department, Medical College Hospitals, from 1934 to 1936:—

Age	Total number
0-2 years ..	9
2-10 " ..	104
10-15 " ..	277
TOTAL ..	390

These numbers do not include the cases detected by a survey of tuberculous homes referred to later on in this paper.

Some years ago, we obtained the following incidence of extrapulmonary tuberculosis among

1,019 cases in a series of 52,550 general patients attending the outdoor departments of this hospital:—

Age	Glandular tuberculosis, per cent	Osteo-articular tuberculosis, per cent
0-5 years ..	7.5	12.5
5-10 " ..	5.0	15.0
10-15 " ..	17.0	12.5

Nobody knows what was in the fate of these children. Although we know that tuberculous disease in infancy and childhood occurs mostly in those reared in a tuberculous environment, yet, fortunately for the human race, infection is only exceptionally followed by disease. Otherwise all the tuberculin-positive infants of this country would be ill with, or succumb to, tuberculosis before reaching adolescence. Tuberculous disease in childhood has a strong tendency to heal and, though most of the infected and diseased escape death, a certain proportion succumb to meningeal or other forms of the disease.

From the mortality figures for England and Wales in 1927 quoted below, it will appear that extrapulmonary tuberculosis, and particularly meningitis, is the chief fatal form of the disease up to five years. Towards the latter end of this period, the tuberculosis scene changes somewhat and the child develops an ability to form fibrous tissue around a tuberculous lesion.

Age	All forms of tuberculosis	Tuberculosis of the respiratory system
0-1 year ..	718	91
1-5 " ..	2,284	378
30-35 " ..	3,485	3,208

In studying the childhood type of tuberculosis in India, it should be borne in mind that the degree of tuberculization of the population in India to-day is still only half of that in European countries and that there is quite a large number of adolescents and adults in remote rural and semi-rural areas who present a 'virgin soil' and thus show, when infected, the childhood type of tuberculosis, as has been previously pointed out by us (Ukil, 1930).

Besides the above cases, we have been able to collect materials from and to study over a dozen cases of fatal tuberculosis obtained from the autopsy rooms of the Medical College Hospitals and the police morgue. Most of them had been wrongly diagnosed, due probably to the absence of a proper perspective in the mind of the average medical man in this country.

Some facts obtained from tuberculous homes
We had recently an occasion to examine and to follow up 444 children belonging to homes

which have or had a definite case of pulmonary tuberculosis under our care at the chest department. The 'contacts' of these cases have not only been examined periodically clinically and with the help of the Mantoux test and skiagraphy, but have been regularly followed up by tuberculosis health visitors. Two-thirds of these children belonged to the poorer classes. We do not propose to go into the whole evidence emanating from this study but shall try to state a few salient features in connection with the present paper. Of these, 343 were in contact with 'open' cases, 27 with 'closed' cases and 74 with 'known sputum' cases. Three hundred and eighty-five had 'intimate' contact, while 61 had 'distant' contact. In 385 of these cases, radiographical examination was done. Among them 15 per cent showed active parenchymal lesions, 8 per cent showed arrested parenchymal lesions and 36 per cent showed grossly enlarged tracheo-bronchial glands. In the remainder no lesions could be detected. The following table gives the radiological evidence in relation to the tuberculin reaction according to age:—

Radiological evidence (383 cases)

Nature of lesion	AGE GROUP (IN YEARS)				Total	Per cent of total cases	Mantoux positive per cent
	0-2	2-5	5-10	10-15			
Active parenchymal lesion.	10	17	26	10	63	16	90
Arrested parenchymal lesion.	1	3	14	9	27	7	88
Enlarged hilar glands.	22	44	45	24	135	36	70
No lesions detected.	18	33	73	36	160	41	73

It has been found that the percentage of positive reaction varies *directly* with age, while the incidence of demonstrable and active lesions varies *indirectly* with age. Active lesions were found more frequently in the younger ages (*vide* graphs, figures 5 and 6).

We have only been able to observe these children through a period of three years. From the history taken for five years, the tuberculosis mortality among children in these homes has been found to be twice as high as the general mortality. This probably is an under-estimate, as a relatively high general mortality rate among infants and children is likely to mask the difference between tuberculosis and non-tuberculosis death rates. Tuberculosis mortality among adults in these homes has been found to be three and a half times as high as general mortality.

One more point remains to be discussed. The investigations of Blacklock, Stanley Griffith and others have shown that in Great Britain about

25 per cent of childhood tuberculosis occur from bovine infection, and are due to drinking the milk of tuberculous cattle. Although we do not yet know all we want to know about the existence of bovine tuberculosis in India, it is certainly much less common here than in European countries. When we consider this along with the fact that people in this country almost invariably boil the milk they drink it makes the possibility of bovine tuberculosis playing an important rôle in the dissemination of tuberculosis among infants and children rather remote. When we consider the following data, in addition to what we gave in a previous paper (Ukil, 1933), there will be no doubt that the contagion from human sources is practically the only method of infection in this country. From the habits and mode of life of the people

Early pulmonary lesions caused by the human type of bacillus in 26 children

Source of material	AGE INCIDENCE	
	0-5 years	5-15 years
Cervical glands	2	10
Axillary glands	1	Nil
Tracheo-bronchial glands ..	3	Nil
Inguinal glands	Nil	1
Mesenteric glands (from autopsy materials).	Nil	2
Bones and joints	2	4
Skin	Nil	1
TOTAL	8	18

Parenchymal lesions in lung (active & arrested) among positive reactors according to age

Fig. 5.

The relationship of the positive Tuberculin reaction to parenchymal lung lesions according to age.

Fig. 6.

in general in this country, it is unthinkable that tuberculous disease, in its various forms, does not contribute substantially to the total mortality figures in infancy and childhood.

Early recognition

From the evidence adduced above, it will appear that the need for the early recognition of tuberculosis in infancy and childhood has

not yet attracted sufficient attention from medical practitioners or from public health workers. No doubt the infection and mortality are much higher in 'home contacts' than in non-contacts. The mortality is particularly high in the first year of life and very much lower afterwards. This is easily understood, as the infant lives strictly within the house and has therefore more chances of contact with a source of infection than an older child who spends more time out of doors. The ultimate prognosis of a case depends not only on the dose and intimacy of contact, but also on the age of the child and the continuance or stoppage of contact. Asserson (1927) observed that 15 per cent of those infected under 12 months and 2.6 per cent of those infected between one to two years of age died of tuberculous disease. Ribadeau-Dumas (1925) gives the mortality after infection in the first three months as 92 per cent, in the first year as 50 per cent and in the second year as 10 per cent.

The three- to seven-year period represents a period of temporary calm, troubled only by occasional cases of meningitis or bone tuberculosis. This temporary calm is followed by the preparation of the 'candidates' for the adult type of tuberculosis.

The difficulties of a timely diagnosis are increased by the fact that the symptoms of childhood tuberculosis are, as a rule, relatively few in the average patient. The manifestations may be entirely absent in cases with advanced and active lesions. Tuberculous disease in infancy and childhood occurs mostly in those raised in a tuberculous environment, i.e., where either a near relative or a nurse or an attendant has been or is a case of 'open' tuberculosis. Crowded living conditions, poverty and defective sanitary habits and customs increase the chances of exposure and disease in India.

The problem of the 'open' adult case in the house is, therefore, of paramount importance not only in diagnosing a case of childhood tuberculosis, but also in isolating the child from repeated large dose infection which hypersensitizes and makes him more vulnerable to the disease process. The isolation, education, and treatment of the adult case are as much important as is the early detection of infection in infancy and childhood.

Some have gone as far as to suggest that every child should not only be tested with tuberculin thrice before he reaches adolescence but also x-rayed for the detection of latent and active tuberculous infiltrations. We have said that 8 per cent of the 'contact' children examined by us showed latent and 15 per cent showed active parenchymal lesions in the lungs. We are not in a position to say what fraction of these will develop into adolescent disease, but some will surely do so if the vicious circle of infection and resistance is not broken.

As a correct interpretation of the Mantoux test and clinical findings is necessary for a correct and uniform diagnosis, we think it will not be out of place to give here a few points about them.

The main points of difference between the childhood and adult type of tuberculosis may be summarized as follows:—

Childhood type

Adult type

- | | |
|--|---|
| <ol style="list-style-type: none"> 1. Usually occurs in children, much less frequently in adults. It is the result of a primary infection. May be localized in part of the lung. 2. Associated tracheo-bronchial lymph nodes are always involved, but may not be demonstrable. 3. Caseous lesions usually become calcified or encapsulated in fibrous tissue. Occasionally a lesion progresses to excavation. 4. Infiltrated areas commonly resolve, leaving trivial or no scars, except for the foci of caseation, which usually become calcified. 5. The prognosis is good. | <ol style="list-style-type: none"> 1. Usually occurs in adults, but may be found in children. Result of a continued infection or a reinfection. Localization is usually in the upper part of the lung. The first clinical manifestation is usually sub-apical. 2. Tracheo-bronchial lymph nodes not grossly involved by the reinfection except sometimes in the terminal stage. 3. Caseous lesions usually followed by excavation or fibrosis or both. 4. Infiltrated areas may recede with the production of more or less fibrous tissue. 5. Prognosis in children is poor. |
|--|---|

The first important point to note about a patient is whether there is a history of exposure. Next, we are to ask about the local and constitutional symptoms, which are less definite and less severe than in adults.

In infants between 6 months to 2 years, the following should be looked for:—

(1) Unexplained anorexia and loss of weight or suspension of growth.

(2) Fever. A persistent fever even after half an hour's rest in bed, when not explained by other verified causes, should lead one to suspect tuberculosis. It should be remembered that athrepsia alone may be present without any fever at all.

(3) Fever and anæmia, often with enlarged spleen and liver. In severe infections, the lung lesion, usually broncho-pneumonia, may be associated with the above, along with the enlargement of superficial glands. Such cases may have to be differentiated from malaria, kala-azar, syphilis and pseudo-leukæmia.

(4) Cough and expectoration. Cough may be altogether absent or may be caused by the pressure of enlarged glands on the bronchi. Stethoscopic signs may be entirely absent or one may hear unilateral, localized, crepitant or sub-crepitant râles or rhonchi. As very few children expectorate before the tenth year, the best way

to demonstrate the presence of tubercle bacilli is to examine for them either from a throat swab, or from centrifugalized stomach wash or fæces.

(5) Sero-fibrinous pleurisy, especially in the mammary region, is frequently present and should be looked for.

(6) Dyspnoea and stridor are observed in many cases of tracheo-bronchial adenopathy. They may be sometimes confused with diphtheria, asthma or enlarged thymus.

When one or more of the above symptoms are present, it is as well to do a Mantoux test, and, if positive, to have a careful examination under the x-ray screen, including the lordosis position, and a skiagram of the chest. A definite involvement of the lung parenchyma or hilum or both, along with a positive tuberculin test, ought to justify a diagnosis of infantile tuberculosis, until otherwise proved. In the case of enlarged superficial glands, syphilis and Hodgkin's disease should be excluded.

In children between 2 to 10 years, the diagnosis should be clinched on a common-sense consideration of a multiplicity of minor symptoms and signs, local and constitutional. The history of exposure having been taken first, a weakly pale child with capricious appetite and failure to thrive, with perhaps some temperature or cough, ought to be looked on with great suspicion. A careful physical examination may show a flat chest or visible veins or enlarged supra-clavicular glands on inspection. The percussion signs, except perhaps the tracheophony of d'Espine's sign to some extent, if properly interpreted, are not of much value. Auscultatory signs indicate nothing else but the presence or pressure of enlarged glands on trachea or bronchi. The Mantoux test should always be done, and, when positive, it should be interpreted as evidence of past infection. It indicates active disease in very young children in cities or in older children in rural and semi-rural areas only when the clinical manifestation of impairment of health is present, along with corroboration by x-ray evidence. It requires a good deal of experience and carefulness in interpreting x-ray evidence of parenchymal infiltration or tracheo-bronchial adenopathy. The interpretation of x-ray pictures should go hand in hand with the history, constitutional symptoms and signs, tuberculin test and laboratory data. In the case of older children, however, it should be remembered that stethoscopic signs may sometimes be present long before radiological evidences are brought forth.

The technique and interpretation of the intradermic tuberculin test (Mantoux) are given in an appendix at the end of this paper in the hope that they may prove useful to physicians and public health workers in investigation and diagnosis. The interpretations are based on

Indian experience of quite a large number of cases in rural, semi-rural and urban areas.

Prognosis and treatment

Barring meningeal complications or intercurrent acute infections, the prognosis in childhood tuberculosis is, generally speaking, favourable. If they are removed from the source of exposure, they respond well to good food, fresh air, sunlight and a hygienic environment. This response, of course, depends, to a great extent, on the patient's relative immunity to infection by the tubercle bacillus, the size and virulence of the dose and the duration of exposure.

The average child with tuberculosis need not be excluded from school but he should have more rest, fresh air and better diet than other children. Those with active diffuse parenchymatous lesions should be institutionalized in a climatic sanatorium until the signs of activity have completely disappeared. It should be remembered, however, that though the childhood lesion may be fibrosed or calcified, there is a danger of its breaking down into adult tuberculosis during adolescence. Every tuberculous child should, therefore, be under medical supervision until the period of adolescence is safely over. Such cases should always guard against over-exertion, both mental and physical, and should try to maintain a good standard of resistance.

Conclusion

It has been stated above that infantile and childhood tuberculosis occurs mostly in tuberculous homes. Do we really possess any idea about the sources of contagion in urban and rural areas in India to-day? Tuberculosis has been declared an infectious disease, notifiable by medical practitioners (but the rule is very seldom enforced), only in municipal areas in three or four provinces. In two more (Bombay and the Central Provinces), the heads of families in municipal areas are required to notify on penalty for non-compliance. Nowhere is it notifiable in rural areas.

The registration of deaths is so defective that the Public Health Commissioner in his report for 1932 (p. 87) made the following remarks:— 'The value of the recorded figures is greatly vitiated by the fact that correct diagnosis of the cause of death is rarely obtained and numerous deaths from tuberculosis are, without doubt, registered both in towns and villages as due to fevers and respiratory diseases. Indeed it may safely be assumed that the majority of deaths from tuberculosis is registered under one or other of these groups'. A large number of deaths reported to be due to fever, bronchitis, etc., has been found on investigation to be really due to tuberculosis. Rogers (1904) and Stewart and Proctor (1906-07) found that, in some rural areas in Bengal, 9 per cent of the deaths reported as due to fever were really

due to tuberculosis. In an inquiry in the suburbs of Calcutta (Cossipore-Chitpur) conducted in 1907-11, it was found that 20 per cent of the deaths entered as due to respiratory diseases were actually due to phthisis and that 50 per cent of phthisis cases were entered as due to fever in public health returns. Lieut.-Col. (now Sir Cuthbert) Sprawson found that, in the Lucknow municipality, 17.2 per cent of all deaths were due to tuberculosis. Dr. A. Sousa, an Assistant Director of Public Health in the United Provinces, found that 19 per cent of all deaths in Allahabad municipality were due to tuberculosis. Major-General Graham stated in 1927 that the mortality from tuberculosis in some large cities exceeded that of certain crowded European cities.

If this is so and if we know that a large number of infants below one year, who have been in contact with tuberculosis cases in the household, succumb to this disease, is it possible that the infants and children of India escape death from tuberculosis in the early age period when the bacilli are implanted on 'virgin soil'? The Public Health Commissioner's report for 1932 states that 40 per cent of infantile mortality are from respiratory diseases, that debility, malformation and premature birth account for another 40 per cent, that convulsions account for 10 per cent and that remittent and undefined fevers account for 2.5 per cent of deaths. Do we know to-day what fraction of these is really due to tuberculosis? Probably because we do not know anything about these, the Public Health returns for mortality do not refer separately to the different categories of deaths from tuberculosis in infancy and childhood (meningeal, miliary, etc.). Can we shut our eyes any more to this state of affairs?

The workers of the public health department cannot get correct returns unless, in the absence of a tuberculosis service in the country, the general practitioners come forward with a proper outlook towards the problem. A proper knowledge on this subject has so long been lacking because we neither possessed special children's hospitals nor tuberculosis dispensaries wherefrom data could be gathered. The very insufficient data which we have been able to produce with a great deal of difficulty, we hope, will convince public health, maternity and child welfare workers and practitioners in general of the importance of detection, registration and prevention of infantile and childhood mortality from tuberculosis. The establishment of tuberculosis clinics in different parts of the country is no doubt a move in the right direction, but what can we expect from only 58 clinics in the whole of India at the present moment? An alert general practitioner can, therefore, do much more to prevent this unnecessary slaughter of infants and children. If this small paper helps to bring about this alertness, we shall deem our efforts amply rewarded.

Acknowledgment

The writer acknowledges with grateful thanks the help that he has received from the authorities of the Medical College Hospitals, Calcutta, the Professor of Pathology, Calcutta Medical College, the Police Surgeon, the Health Visitors of the Tuberculosis Association of Bengal, Dr. P. K. Sen and from his staff at the Chest Department and at the All-India Institute of Hygiene and Public Health in working upon and in mobilizing the materials used in this paper.

APPENDIX

The technique and interpretation of the intradermic tuberculin test (Mantoux)

The Mantoux test is more accurate than the cutaneous and other tests in that a known amount of tuberculin can be given and the dose increased, if desired. For this reason, a slightly larger number of reactions can be obtained than with the cutaneous test of von Pirquet. It has been shown that the Pirquet test may be considered to be equivalent to 0.1 c.cm. of a 1/1,000 dilution (= 0.1 mg.) of Old Tuberculin (O.T.) administered intradermally, so that when 1/10,000 dilution is employed the Pirquet test may be more sensitive when a reliable brand of undiluted O.T. is used for the latter. By the intracutaneous method, any two successive tests, done in graded doses, can be compared, which is not possible with the cutaneous test. The International Standard Tuberculin is recommended for general use.

Technique of the test

Use International Standard Tuberculin or preferably the new Purified Protein Derivate (P.P.D.), the active principle of O.T. isolated in pure form.

Use sterile, normal saline or 0.2 per cent carbolyzed saline for dilution in such a way that 0.1 c.cm. contains the desired dose. Dilutions should be kept in the ice chest and never employed when more than a fortnight old.

The following dilutions are generally employed:—

1/10,000, 1/1,000, 1/100, and 1/10. A well-fitting 1 c.cm. syringe graduated in 20ths with a short, bevelled, intradermal needle is required. The syringe, once filled, holds fluid for 10 tests, the needle being merely wiped with cotton wool soaked in absolute alcohol or flamed between the injections. It is well to have a separate syringe for each dilution.

Injection.—Clean the front of the forearm with rectified spirit and allow to dry. Stretch the skin by holding the forearm taut from below, select a point away from superficial veins, insert the needle into the dermis at the smallest angle possible with the bevel upwards and inject 0.1 c.cm. of the dilution. The injection, if properly made, should raise a white bleb, on the surface of which the hair follicles are easily visible. Subcutaneous injections should be avoided as

they may give rise to general febrile reactions. No controls are necessary up to 1/100 dilution. In case of 1/10 dilution, it is better to keep a control with glycerinated veal peptone broth of the same strength, to avoid atypical non-specific reaction.

Dosage.—The initial dose may be 0.1 c.cm. of 1/1,000 dilution (which is sometimes called the 'standard dilution'), except for patients

- (a) suspected of having bone, joint, ocular and skin tuberculosis or in children with visible cervical nodes, ulcerations or discharging sinuses,
- (b) who have had a recent hæmoptysis,
- (c) who are home-contacts of tuberculosis,
- (d) where their attendance for further tests can be guaranteed, and

(e) who are very young infants, in which case it is advisable to employ the 1/10,000 or an even higher dilution.

Whichever dilution is employed, read result at the end of 48 and 72 hours. If negative, employ the next stronger dilution at the last visit (i.e., at the end of 72 hours). The delay between two tests should not be more than a week. In a large majority of cases, a dilution of 1/100 suffices, but if this gives a negative result a dilution of 1/10 may be employed as the practicable upper limit, as stronger solutions are likely to give non-specific reactions. In case of doubtful reactions, employ the next stronger dilution to settle the result. No test is complete without using the 1/100 dilution, especially for mass investigations.

Reading of the reaction

Reactions should be read at the end of 48 hours. If negative, they should be re-examined at the end of 72 hours, and if still negative, at the end of 96 hours, when a final opinion might be put down. To read, hold the arm slightly flexed at the elbow and in good light and look across the arm rather than down on it.

A test should be recorded as positive or negative to the given dilution. A positive reaction is indicated by œdema and redness around the site of inoculation. When in doubt, feel with the fingers and gently palpate between them. Its intensity is judged by the amount of œdema (its extent and thickness) and redness and by any elevation of temperature and malaise, if they occur. The area of redness is usually less important than the œdema. In measuring the area of erythematous infiltration of the skin (as judged by palpating between two fingers), reactions with the greatest diameter below 5 mm. are regarded as negative. Four categories or degrees of intensity of the reaction are considered, viz:

One plus (+) reaction = slight but defined œdema raised about 1 mm. above skin surface and not more than 10 mm. in diameter.

Two plus (++) = well-defined œdema, raised somewhat more than 1 mm. above skin surface; diameter between 10-15 mm.

Three plus (+++) = more extensive œdema with diameter exceeding 15 mm. and thickness exceeding 1.55 mm. above skin surface; wide area of redness beyond but no vesiculation or necrosis of the skin.

Four plus (++++) = characterized by extensive œdema, redness, vesiculation and necrosis; may be associated with temperature and malaise.

Interpretation

A positive tuberculin test always means the presence of tuberculous infection.

The positive reaction has its chief value in infancy, when it is more likely to be associated with active tuberculous disease that may lead to a fatal issue. The younger the age, the worse the prognosis.

An infant under 2 years showing a positive reaction, but without symptoms, should be kept under observation for some years on account of the possible development of clinical tuberculosis. Meantime the prognosis should be optimistic, though guarded. If, however, obscure and persistent symptoms like unexplained pyrexia or loss of weight are present, the origin might probably be tuberculous and a more serious view should be taken until time shows this to be unwarranted.

A positive reaction in a child aged 2 to 5 or even 10 years with persistent symptoms should suggest that these symptoms are tuberculous in origin. A weightage towards positive significance in interpretation should be given in cases of children in rural and semi-rural areas. An infected or improperly immunized adult in a remote rural area in India may, however, behave like an urban child with regard to hypersensitiveness.

Where a patient over 5 years gives a positive reaction to a qualitative test, it must not be concluded that clinical tuberculosis is present. In such cases, the positive reaction has its principal diagnostic value when elicited by quantitative intracutaneous tests made with weak solutions of tuberculin (e.g., by 1/50,000 and 1/100,000 dilutions), especially in rural people or hill tribes and in dermatological conditions. Quantitative tests are of doubtful value for estimating the prognosis in clinical tuberculosis.

The principal application of tuberculin tests in clinical practice is for a negative diagnosis or the exclusion of clinical tuberculosis. Failure to get a positive reaction does not always exclude tuberculosis. In spite of harbouring living tubercle bacilli in the body, a negative test may be obtained where the dose of tuberculin has been too small to elicit a reaction or the reaction has been done during the ante-allergic period or where the immunity is depressed or absent in certain clinical conditions like acute infectious diseases, pregnancy, cachexias and advanced tuberculosis a few days before death, or in acute miliary or generalized tuberculosis.

Tuberculin tests are of great value in 'contact' cases, both for detecting infection in infants and for excluding tuberculosis in these and older children. In testing contact children of tuberculous families, make a routine test on negative cases at six monthly intervals, to determine the time when they are infected. Children still negative at 4 to 5 years may be given a good prognosis. The prognosis should be guarded when infants under 2 years react positively and when obscure symptoms persist for some time. A positive reaction in a young child aged 2 to 5 or even 10 years with persistent symptoms should suggest that these symptoms are tuberculous. About this age, children who give a positive reaction to 1/10,000 or weaker dilutions should be viewed with suspicion and should be x-rayed. If impaired health and conspicuous underweight are noticed in these children, they should receive special care in diagnosis and treatment. If several positive reactors are found among the children in a family, suspect a 'carrier' in the house.

THE INCREASING VALUE OF MODERN SANATORIUM TREATMENT AS JUDGED BY THE AFTER-HISTORIES OF THE PATIENTS

By C. FRIMODT-MÖLLER, M.B., Ch.B. (Copenhagen)
Medical Superintendent, Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle

MODERN sanatorium treatment differs in many ways from sanatorium treatment of earlier days, not in the principles of treatment but in the way of carrying them out. The ability to carry them out in a better way than formerly is the cause of the increasing value of the treatment, as may be seen specially in the results of treatment of many of the most advanced cases, previously not benefited by it.

It remains as true as ever that the earlier a case of pulmonary tuberculosis comes under proper treatment, the shorter is the length of treatment necessary and the better the results obtained. Nevertheless, in the last few years sanatorium treatment has developed so rapidly that now it is often in many of the most advanced and desperate cases that very striking results are obtained.

The increasing value of modern sanatorium treatment is obvious from the immediate results of treatment, but is much more convincingly borne out by an investigation of the after-histories of the patients, which investigation shows that the results obtained at the time of discharge are not only better, but more lasting.

It may not be out of place, before going into the question of the after-histories, to summarize briefly what we mean by modern sanatorium treatment as compared with sanatorium treatment in former days.

The principle of sanatorium treatment—the very backbone of it, so to speak—is the change between rest and graded exercise in the right proportion in each individual case. The control of this change depended previously only upon the observation of the various clinical symptoms of the patient and the stethoscopical examination of the lungs. The modern sanatorium treatment has added two more very important methods of controlling the change. The first of these is the x-ray examination by x-ray photos and by fluoroscopic examinations of the chest, each supplementing the other.

The second method is various blood examinations. In our opinion repeated blood examinations give more valuable information with regard to the control than any of the other methods.

Advances have been made not only in the control of the treatment but even in the treatment itself—in the ability to produce rest for a diseased lung to an extent never thought of before. Formerly, the only way of creating rest for the lung was to keep the patient in bed which, at the best, only provided a very partial rest and was in consequence totally insufficient in many cases. In the modern treatment it is possible to give rest to the lung inside the patient by, as it were, bandaging the lung and so preventing its movement. This immobilization is created by various forms of modern lung surgery.

While in the drug treatment of the disease comparatively little advance has been made, yet in the use of gold salts there has been found a remedy which in selected cases, specially when combined with artificial pneumothorax treatment, has proved to be of great value.

That the widening field of the usefulness of modern sanatorium treatment is gradually being understood is shown by the increasing number of admissions to the sanatoria, from year to year, of patients in the most advanced stage of the disease, which is a feature found all over the world. The increased admission of patients in the third stage of the disease is also seen in this sanatorium, as shown in the following table:—

TABLE I

The stages of the disease in 4,308 patients admitted during 1916 to 1935

Five-year periods	Patients admitted	I stage, per cent	II stage, per cent	III stage, per cent
1916-20	807	29.5	46.5	24.0
1921-25	737	19.8	25.6	54.6
1926-30	1,231	22.5	24.3	53.2
1931-35	1,533	15.9	16.9	67.2

It will be noticed from table I that during the last 15 years more than half the patients admitted were in the most advanced stage. During last year, 1935-36, even 72.2 per

cent of the patients admitted were in the third stage.

The ability of the discharged patients to survive and to return to their normal conditions of life is the final test of the real value of sanatorium treatment which cannot be judged merely by the immediate results obtained at the time of discharge. For the purpose of such a test an investigation of the after-histories of the patients over a period of five years is sufficient. The reason for this is that investigations in the West, as also our own, have shown that the greatest number of patients who die after discharge die within the first two years after leaving the sanatorium, and that patients living more than five years rarely die of tuberculosis. We find that of 2,390 patients discharged during 19 years, whose fate is known, 680 died, but of these not less than 561 died within the first two years. Only 30 of them died of tuberculosis after a period of five years.

Everyone familiar with Indian conditions will understand the difficulty of tracing many of the patients after they have left the sanatorium. We have, nevertheless, been able to collect information of about 1,695 out of 2,604 patients who have been treated more than one month in the sanatorium, being therefore included in the medical statistics, and who have been away from it for at least five years after discharge. We believe that this considerable number of untraceable patients does not, however, affect the reliability of our investigation to such an extent as one might be inclined to think at first. The reason for this belief is deduced from the figures given in table II.

From this table it will be seen that the untraceable patients are distributed approximately in the same proportion over the three stages and over the immediate results on discharge in each stage.

The percentage of untraced patients is 34.9 for the whole group of 2,604 patients discharged during 1916 to 1930, and in most of the stages and in their subdivisions the percentage is almost the same. Although this comparatively large percentage of unknown results is unsatisfactory, yet we have to work with the facts available in order to get some information about the after-results of the treatment, and, in our opinion, from what we have stated above, there is

TABLE II

Immediate results on discharge of 2,604 patients treated during 1916 to 1930

			Arrested	Much improved	Improved	Worse	Total number
I stage, 648 patients ..	{	Traced	340	66	24	11	441
		Untraced	151	33	18	5	207
II stage, 840 patients ..	{	Traced	180	188	62	74	504
		Untraced	91	132	57	56	336
III stage, 1,116 patients ..	{	Traced	8	231	163	348	750
		Untraced	8	105	69	184	366

reason to suppose that the proportion of living and dead would not be materially different in the untraced group of patients from what it is in the traced one.

Confining ourselves to the traceable patients we find that out of 1,695 patients who have been away from the sanatorium at least for five years, 898 or 53.0 per cent were alive after five years. Of these patients 819 were doing full work. These figures include the most advanced cases.

The value of modern sanatorium treatment is, after all, not brought out quite satisfactorily in this way by considering the percentage of patients living five years after discharge out of the total number of patients, irrespective of the stage of the disease they were in on admission and of the results of treatment obtained at the time of discharge. It is brought out far better by taking these facts into consideration which are done in the following table:—

five years after, and of those discharged as 'improved' as many as 25.1 per cent.

The great progress in the usefulness of the modern sanatorium treatment is, however, best demonstrated by considering each of the three five-year periods separately and comparing the results. In doing this we have grouped together as 'clinically well' those patients discharged as 'arrested' and 'much improved' in each stage, as we have already seen from table III that these are the patients who at the time of discharge have the best prognosis for the future.

There are some interesting facts to be derived from a study of this table.

The first one is the increasing percentage of those discharged as 'clinically well' through the four quinquennial groups, the only exception being those discharged in the II stage during 1926 to 1930.

The second interesting fact is that this improvement in the immediate results of treatment is a real one as proved by the after-histories.

TABLE III
The after-histories of 1,695 patients traced five years after discharge

	ARRESTED			MUCH IMPROVED			IMPROVED			WORSE		
	Traced	Living	Per cent	Traced	Living	Per cent	Traced	Living	Per cent	Traced	Living	Per cent

1916-30	180	152	84.4	188	135	71.8	61	30	49.2	75	13	17.3
III stage												
1916-20	3	1	..	28	10	35.7	25	3	12.0	62	2	3.2
1921-25	2	2	..	62	35	56.5	64	16	25.0	137	2	1.5
1926-30	3	3	..	141	90	62.9	74	22	29.7	149	2	1.3
1916-30	8	6	..	231	135	58.4	163	41	25.1	348	6	1.7

From a study of table III it will be seen that of the patients in first stage discharged as 'arrested', not less than 90.3 per cent were living five years after leaving the sanatorium, of those discharged as 'much improved' 81.8 per cent and of those discharged as 'improved' 79.2 per cent.

In second stage the corresponding percentages are 84.4, 71.8 and 49.2.

In third stage the number of 'arrested' is too small for the percentage to be of value. Of the patients in this, the most advanced stage, we find that of those discharged as 'much improved' not less than 58.4 per cent were living

The more lasting effect of the immediate results of treatment is specially to be observed among the patients in III stage who are the most advanced and often desperately sick cases. It is a great improvement that in the 1926 to 1930 group 34.3 per cent are discharged as 'clinically well' compared with 23.1 in 1921 to 1925 and 24.7 in 1916 to 1930, but this improvement is nearly doubled in permanence in the last group where it is seen that 64.6 per cent are alive and well five years after discharge compared with 35.5 per cent in the group 1916 to 1920. From this it will be understood how much more lasting is the improvement which is gained under modern sanatorium treatment.

TABLE IV

2,291 patients discharged as 'clinically well' with their after-histories

Years	I STAGE					II STAGE					III STAGE				
	Number of patients discharged as 'clinically well'	Per cent	Number of those traced	Number living five years after discharge	Living per cent	Number of patients discharged as 'clinically well'	Per cent	Number of those traced	Number living five years after discharge	Living per cent	Number of patients discharged as 'clinically well'	Per cent	Number of those traced	Number living five years after discharge	Living per cent
1916-20	207	86.9	129	109	82.9	235	62.7	141	100	70.9	48	24.7	31	11	35.5
1921-25	122	93.1	105	93	88.6	135	73.6	88	75	85.2	84	23.1	64	37	57.8
1926-30	247	94.8	172	159	92.4	217	76.3	139	112	80.6	211	34.3	144	93	64.6
1931-35	203	95.3	192	81.0	390	38.5

It is most encouraging that it is now possible to say that more than half the number of patients in the most advanced stage, if treated in an up-to-date sanatorium and discharged as 'much improved', will probably live and work five years after discharge, and we know that if they live so long, they will probably not die of tuberculosis.

The fact that so much can now be done for patients in the advanced stage of tuberculosis, when treated in an up-to-date sanatorium, is not fully realized by the medical profession, nor is it widely known by the tuberculous patients themselves. The result of this is that many patients in the advanced stage, instead of getting the proper treatment, succumb to the disease continuing to their death to be the most dangerous sources of infection to their surroundings and to the public at large.

Summary

1. It is shown that modern developments are making sanatorium treatment of increasing value. This is demonstrated by considering—

(a) the immediate results of treatment on discharge of 4,308 patients treated during the years 1916 to 1935.

(b) the after-histories of 2,604 patients, that is, omitting from the 4,308 patients 1,533 who have not yet been away five years from the sanatorium, and 177 who died before discharge in the years 1916 to 1930.

2. Out of 2,604 patients discharged during 1916 to 1930, 1,695 were traced. For reasons given the untraceables are omitted in the statistics analysed.

3. Of the 1,695 patients traced 898 or 53 per cent were alive five years later and 91 per cent of these were doing full work.

4. The value of modern sanatorium treatment is better and more correctly brought out by considering the after-histories in relation to the stage of the disease and the results of treatment on discharge. In I stage of those discharged as 'arrested', 'much improved' and 'improved', 90.3, 81.8, and 79.2 per cent respectively were alive five years after discharge: in II stage 84.4, 71.8, and 49.2 per cent: in III stage of those discharged as 'much improved' 58.4 per cent and of the 'improved' 25.1 per cent.

5. Consideration of the patients divided into four quinquennial periods emphasizes the improvement of results which had followed modern development of treatment. There is seen a steadily increasing percentage from period to period of those discharged as 'clinically well' (that is 'arrested' and 'much improved' grouped together); in I stage the figure being 95.3 per cent for the period 1931 to 1935 as compared with 86.9 per cent for the period 1916 to 1920; in II stage 81.0 per cent as compared with 62.7 per cent; and in III stage 38.5 per cent as compared with 24.7 per cent for the same periods.

6. Most striking is the increase in the lasting effect due to modern treatment. This is seen best of all among the most advanced cases. Of those discharged as 'clinically well' as many as 64.6 per cent of the period 1926 to 1930 were living five years after as compared with 35.5 per cent from the period 1916 to 1920 and 57.8 per cent from 1921 to 1925.

7. Modern sanatorium treatment is increasingly able to save the lives of tuberculous patients, even a great many of those in the most advanced stage of the disease, and to return them to normal conditions of life in a way which was absolutely impossible in earlier days.

SOME OBSERVATIONS ON CHRYSOTHERAPY IN PULMONARY TUBERCULOSIS

By J. C. BANERJEA, M.B. (Cal.), M.R.C.P. (Lond.)
Honorary Junior Visiting Physician, Medical College
Hospitals, Calcutta

It is just a decade since Mollgaard of Copenhagen discovered the gold treatment of pulmonary tuberculosis in 1924. Great enthusiasm swept over the medical world and the sanocrysin treatment of Mollgaard was taken up by the specialists in tuberculosis of nearly every country with high hopes of success, but, as time passed on, the enthusiasm gave place to depression. Follow-up of the cases treated in the earlier years revealed unfavourable results at the hands of nearly all the experts and so the treatment was given up for the time being. The French school, however, headed by Leon Bernard and Dumarest, persisted in this method of treatment, using gold salts of lower toxicity than sanocrysin and in smaller doses. They have reported favourable results in 50 to 60 per cent of cases, but the experiences of other workers on this method of treatment differ widely and in spite of so much work the value of gold treatment remains still unproven.* In America it is much less thought of and less utilized. But in India we find that gold treatment is being tried with great zeal both by general practitioners and by specialists. It is high time that we should be using this method of treatment with caution and discretion and should pause to take stock of our experiences from time to time. With these thoughts in mind I took up the present study which is based on personal observations in a series of sixty cases.

Selection of cases

It is essential to remember that the whole success or failure of chrysotherapy depends on the selection of cases. It is unanimously agreed that (1) cases with recent exudative lesions are most suitable for gold therapy. Only a few cases, however, are seen by us at this stage, and, if we limit the use of gold salts to this group, we shall find that about 10 to 20 per cent of cases will receive this treatment. With

discretion the treatment may be extended to (2) a second group where it is desirable to collapse one lung by artificial pneumothorax or phrenic evulsion and to check the progress of recent lesions in the other lung. There is yet a third group (3) where the use of gold salts has been advocated to check the acute exacerbations of a chronic fibrotic type of case.

Contra-indications

It must be emphasized that cases showing markedly toxic symptoms with high fever, gastro-intestinal lesions and renal lesions, as well as cases with marked emaciation, are not suitable for chrysotherapy. I would like to point out that cases with recurrent attacks of hæmoptysis are unsuitable for gold treatment, though many workers do not think hæmoptysis to be a contra-indication. Involvement of the larynx by itself does not contra-indicate the use of gold salts and I have had one such case where the pulmonary and the laryngeal lesions showed considerable improvement under chrysotherapy and the improvement has been maintained till now, a period of one year.

In my series the cases selected for chrysotherapy may be grouped as follows under five headings:—

- | | | |
|--|----|----|
| (1) Recent exudative cases | .. | 13 |
| Unilateral | .. | 4 |
| Bilateral | .. | 9 |
| (2) Cases suitable for artificial pneumothorax which however could not be induced because of pleural adhesions | .. | 6 |
| Unilateral | .. | 4 |
| Bilateral | .. | 2 |
| (3) Advanced cases unsuitable for artificial pneumothorax | .. | 19 |
| (4) Cases where artificial pneumothorax was carried out on one side and gold treatment resorted to for checking the progress of recent lesions on the other side or to promote healing of uncollapsed diseased areas | .. | 17 |
| (5) Phrenic evulsion cases | .. | 5 |

Mode of action of gold salts

The mode of action of gold salts in pulmonary tuberculosis is obscure. Mollgaard's original idea that gold salts have a direct bactericidal action *in vivo* has not been confirmed by experimental observations. Feldt believes that gold accelerates the complex defensive mechanisms of the host by an activation of the cells of the reticulo-endothelial system which is chiefly concerned in the production of immunity. Apart from these theories, there are certain demonstrable effects on the blood, such as (1) decrease of the sedimentation rate of the erythrocytes, (2) increase of total leucocytes with lymphocytosis and decrease or slight increase of monocytes. These blood changes

*The author's conclusions are based chiefly on cases treated with intramuscular injections of solganal B. oleosum; comparative figures for cases without gold therapy have not been included as controls. Many workers in India, particularly those at the Madanapalle Sanatorium, will not subscribe to the author's statement that 'the value of gold treatment still remains unproven'. The success of gold therapy, particularly with intravenous injections of sanocrysin, depends not only on the selection of cases but also on careful observation by repeated examinations of the urine, on the blood-sedimentation index, and on other tests. Because it requires great care in the selection of cases and management of treatment, gold therapy should not be condemned. Even in the author's series, 58 per cent of the cases showed definite improvement.—EDITOR, I. M. G.

are favourable. There are other changes which are unfavourable and in such cases gold salts should be stopped. These are (a) rise of the polymorphonuclear count and eosinophilia, and (b) diminution of the blood platelets.

Preparations and mode of administration

There are various preparations of gold salts on the market and any of the following may be used provided the dosage is carefully regulated :—

Sanocrysin (double thiosulphate of gold and sodium).

Crisalbine.

Solganal B.

Oleo-sanocrysin.

Solganal B. oleosum.

In the present series of cases I used solganal B. oleosum in 55 cases, oleo-sanocrysin in 3 and lopian in 2. One cannot definitely lay down a scheme of dosage which will suit all cases. The dosage and interval have to be modified according to (a) the general condition of the patient, (b) weight of the patient, (c) extent and type of disease and (d) reactions of the patient. In a febrile case it is desirable to begin with a small dose 0.002 gm. by the intramuscular route and increase it by 0.002 gm. at intervals of four to six days, provided no reactions supervene. In an afebrile case we may start with 0.01 gm. and use double the dose every week till 0.4 gm. is reached and this last dose is repeated at weekly intervals until a total dosage of 5 to 6 gm. is administered. Then, after an interval of two months, a second course of 5 gm. is given, if necessary. Unfortunately it has been found that many cases cannot tolerate gold injections, even in very low dosages. In others, 20 per cent in my series, treatment had to be abandoned in the middle of a course because of unfavourable reactions, such as rise of temperature of more than two degrees above the previous level and continued for more than a week, hæmoptysis, stomatitis and dermatitis. In the early years when dosage was high, severe reactions were frequent. Now, we generally use a low or moderate dosage. K. Secher (1931) however believes that many poor results of gold treatment are due to the low dosage and therefore he advocates larger dosages which cause some reaction.

The complications that might arise during chrysotherapy have been stated to be numerous, viz:—

(a) Febrile reactions.

(b) Gastro-intestinal—ulcers of mouth and lips, loss of appetite, nausea, vomiting, and diarrhœa.

(c) Circulatory—collapse.

(d) Renal—albuminuria, red blood cells and casts in urine.

(e) Hepatic—jaundice.

(f) Joint complications.

(g) Skin—rashes—morbilliform, erythematous, or purpuric [22 cases recorded recently in literature (Hudson, 1935)]; herpes, pruritus or pigmentation.

In the past, when larger dosages were used, the complications were frequent, but with the use of smaller dosages and of oily preparations they are few and mild. The commonest that I have come across have been febrile reactions and mild gastro-intestinal symptoms. In one case, I saw an erythematous rash all over the body, more marked on the extremities, on the third day after injection. In another, I have seen slate-grey pigmentations of the skin of the back and the abdomen appearing after the seventeenth injection and persisting for over three years. In a third I have seen severe stomatitis and gingivitis. Apart from the occasional appearance of albumin in the urine I have not seen any marked renal complication.

Results of chrysotherapy

It is extremely difficult to assess the value of any anti-tuberculous remedy unless we adopt the same criteria of clinical improvement or cure. A patient is clinically considered to be cured when there is anatomical healing with disappearance of toxæmia and return to normal living and working conditions. Results of any method of treatment should be assessed at the end of five years, if not at the end of ten years. Hence a follow-up of the treated and untreated cases is essential for the evaluation of chrysotherapy. From this point of view my observations are not likely to yield much valuable information inasmuch as they have been made during the last five years. Still the results of gold treatment in my series of 60 cases are presented for the consideration of my medical colleagues.

It will be seen from the table (p. 207) that about 58 per cent of cases showed definite improvement under chrysotherapy. These results agree closely with those of Mayer (1934) who reports improvement in 66 per cent of his 404 cases and with those of Bernard (1932) who reports favourable results in 50 per cent of his series. Even if we leave out of our consideration the cases of temporary improvement we find marked improvement in 25 per cent of the present series. Peters and Short (1935) however have recently published a controlled statistical study on the results of chrysotherapy in the age group 16 to 26 during the last five years and they conclude that gold treatment is of no appreciable value. Regarding the effects of chrysotherapy on the sputum it may be interesting to point out that bacilli disappeared only temporarily and they were present some time or other in about 40 per cent of the cases who received a fairly adequate dose of gold salts.

Results of chrysotherapy

Types of cases	Number	RESULTS			Death in all groups
		Marked improvement, i.e., well for two years	Improvement, i.e., well for six months	No improvement	
I. Recent exudative cases	13	6	6	1	1
II. Cases where A P failed	6	0	2	4	4
III. Cases where A P considered unsuitable.	19	1	6	12	7
IV. A P cases with gold treatment.	17	6	4	7	6
V. Cases of phrenic evulsion with gold treatment.	5	2	2	1	2
	60	15 (25%)	20 (33%)	25 (42%)	20 (33%)

resonance over the left base with diminished breath sounds and a few crepitations. Radiogram of the chest before gold treatment (plate IV, figure 1) showed exudative infiltration left middle and lower zones and over the right middle zone. Another radiogram (plate IV, figure 2) taken after the administration of a total dosage of two grammes of solganal B. oleosum by the intramuscular route showed clearing up of the infiltrations to a very great extent.

Case 2.—S. M., boy, aged 20 years, came under observation with fever 100°F. to 101°F., cough and hæmoptysis for two years. A history of contact was present. Clinical examination revealed impaired resonance over right upper zone with diminished breath sounds and a few crepitations. The left lung showed harsh breathing. Sputum showed numerous tubercle bacilli. He was given a total dose of 4.1 gm. of gold salts in the form of solganal B. oleosum in the course of three months. Sputum was free from tubercle bacilli in eight months and there was a gain of one stone and six pounds in weight in the course of one year. A comparison of the radiogram (plate IV, figure 3) taken before treatment with the one (plate IV, figure 4) taken nine months after the completion of a full course of chrysotherapy showed almost a complete resolution of the extensive homogeneous opacity of the right upper lobe, leaving a few strands of fibrosis with some traction of the mediastinum. There was also a complete disappearance of the infiltrations over the left middle zone.

Case 3.—P. S., female, aged 21 years, was seen in October 1931 with fever 99°F. and 100°F., and cough of about one month's duration. There was a history of exposure to an open case of pulmonary tuberculosis in the family. Physical examination revealed impaired resonance, bronchial breathing and crepitations over the infra-clavicular and the axillary regions of the left lung and impaired resonance with weak breath sounds over the base of the right lung. Sputum showed tubercle bacilli in large numbers. The x-rays (plate V, figure 5) showed a cavity over the left upper zone with infiltrations over the upper and middle zones of the same side, few exudative infiltrations over the middle zone of the right side and pleural thickening over the right base. Artificial pneumothorax was tried on the left side but failed due to pleural adhesions. A phrenic evulsion was done on the left side. Three months after the operation the patient was still having a temperature of 99.4°F. in the evening with cough and expectoration. Sputum was still positive to tubercle bacilli. Gold injections were started and a total dose of six grammes was given in the course of five months. At the end of the course sputum was negative to tubercle bacilli. There was a considerable gain in weight. A comparative study of the radiograms taken before and after gold treatment (plate V, figures 6 and 7) showed a marked clearing up of the lesions, both of left and right, with almost a complete disappearance of the cavity over the left sub-apical area. The patient is

well and active till now and the sputum has remained negative persistently for about four years and a half.

Comments

It may be argued that the first two cases cited above are examples of exudative pulmonary tuberculosis of a benign nature and that resolution might have taken place even without resort to chrysotherapy. But it is possible that in these cases gold salts accelerated the natural process of healing by resolution. The beneficial effects of gold therapy in the third case were, however, very striking and it is doubtful whether such a marked improvement would have been effected so quickly by the phrenic evulsion alone combined with the conservative treatment of rest, fresh air and good food.

Summary

From an analytical study of 60 selected cases treated with gold salts it appears that marked improvement occurred in about 46 per cent of the cases with recent exudative lesions and in 25 per cent of the whole series. Such results are obtainable only when chrysotherapy is considered not as the sole curative agent but as an aid to the conservative regimen of rest, good food and fresh air or to some form of collapse therapy, such as artificial pneumothorax, phrenic evulsion and localized thoracoplasties.

In conclusion, I take this opportunity of offering my sincerest thanks to Lieut.-Col. E. H. Vere Hodge, i.m.s., Professor of Medicine, Medical College, Calcutta, for his valuable suggestions and to Lieut.-Col. T. C. Boyd, i.m.s., Superintendent, Medical College Hospitals, for his kind encouragement. My thanks are also due to Lieut.-Col. B. G. Mallya, i.m.s., Superintendent of the Howrah General Hospital, for his kind permission to utilize the case records of the tuberculosis ward of the hospital.

AN ANALYSIS OF ARTIFICIAL PNEUMOTHORAX TREATMENT IN 1,039 PATIENTS

By C. FRIMODT-MÖLLER, M.B., ch.B. (Copenhagen)
Medical Superintendent, The Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle
 and

M. C. VERGHESE, M.B., B.S. (Andhra)
Junior Assistant

IN this analysis the results of artificial pneumothorax treatment tried in 1,039 patients treated in the Union Mission Tuberculosis Sanatorium, Arogyavaram, and discharged between 1921 and 1st October, 1936, are reviewed. This analysis reveals not only the value of this treatment under Indian conditions in a very convincing way, but brings out as well several facts regarding the indications for it which should be of great interest to doctors in India. Many of them do not know which patients are most in need of pneumothorax treatment, nor do they understand that many patients attacked by the disease in both lungs simultaneously can still benefit considerably from it.

The basis of the analysis

It is of little use to judge a certain kind of treatment without giving it sufficient time to produce its effect, if the nature of the disease

anyone with experience of pulmonary tuberculosis will know how often such an improvement turns out to be merely temporary without any real influence on the ultimate progress of the disease. It is therefore necessary for at least three months to elapse before the real value of any form of treatment can be judged.

The 1,039 patients included in this analysis are divided into two groups, the one comprising 690 patients who have been treated more than three months, and the other 349 patients who were selected for pneumothorax treatment but who could not receive it on account of lack of free space in the pleural cavity due to adhesions. Apart from the pneumothorax treatment these two groups of patients lived and were treated under exactly the same conditions. Therefore the second group can reasonably be used as a control group for judging the value of pneumothorax treatment.

The general results

The general results of the treatment as compared with the results obtained in the control group are tabulated in table I, according to the stages of the disease of the patients on admission.

It will be seen from the table that 959 out of 1,039 patients selected for pneumothorax treatment were in III stage. There were, however,

TABLE I

The results of pneumothorax treatment in 690 patients as compared with those in a control group of 349 patients

Stage	Number of patients	ARRESTED		MUCH IMPROVED		IMPROVED		STATIONARY		WORSE		DIED	
		No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent

II	Treated with A. P. 50	2	4.0	38	76.0	4	8.0	1	2.0	4	8.0	1	2.0
	Controls 24	12	50.0	5	20.9	2	8.3	3	12.5	2	8.3
III	Treated with A. P. 637	318	42.9	124	19.5	63	9.9	73	11.5	59	9.2
	Controls 322	84	26.1	47	14.6	81	25.2	58	18.0	52	16.1

Of the patients treated with pneumothorax 71 per cent obtained 'positive results' while of those not treated with it only 43 per cent.

is such that no speedy curative result can be expected of any treatment. In a disease like pulmonary tuberculosis no definite progress towards health can be obtained unless fibrotic tissue has been formed in and round the tubercular foci in the lungs sufficiently to wall them in, thereby preventing the tubercle bacilli and their products from penetrating into the surrounding tissue or from flowing into the blood circulation. This process of formation of fibrotic tissue takes considerable time.

It is quite possible with many remedies to get, within a few weeks, an almost dramatic improvement in the symptoms of the disease but

6 patients in I stage and 74 in II stage whose disease was of such an active nature that pneumothorax treatment became indicated.

In the table very few patients are classified as 'arrested', but this is not surprising considering that the disease in the patient treated was of a very severe type, nor is it disappointing when we know that a great many patients discharged as 'much improved' have great prospect of doing well in later life. This is shown by another investigation where 58.4 per cent of III stage patients discharged as 'much improved' are found to be alive and well five years after discharge.

A study of table I reveals, further, that of the patients that received pneumothorax treatment 71 per cent obtained 'positive results', as compared with only 43 per cent in the control group.

The greatest difference between the two groups is seen in the patients in III stage where 49.9 per cent of those treated with pneumothorax were discharged as 'much improved' as against 26.1 per cent in the control group. This is a most striking demonstration of the value of this form of treatment.

Equally convincing facts are brought out by considering the results of the treatment with regard to the disappearance of fever and of tubercle bacilli from the sputum. This is shown in table II.

The importance of instituting pneumothorax treatment while one lung only is attacked is brought out very strongly in this table where it is seen that of the patients in the group with no disease in the contralateral lung, 88.5 per cent obtained 'positive results' as against 48.9 per cent in the group where both lungs of the patients were affected.

It would, nevertheless, be a great mistake to think that pneumothorax treatment cannot be given with beneficial results in many patients whose two lungs are attacked. The very fact that 48.9 per cent of such patients obtained positive results by pneumothorax treatment, as against 34.7 per cent of those with both lungs affected in the control group, is a proof of its

TABLE II

Results of pneumothorax treatment of 690 patients compared with 349 control cases with regard to the disappearance of fever and of tubercle bacilli from sputum

	DISAPPEARANCE OF FEVER			DISAPPEARANCE OF TUBERCLE BACILLI FROM SPUTUM

	Number	Number	Per cent	Number	Number	Per cent
690 patients treated with pneumothorax.	577	369	63.8	669	364	54.4
349 patients selected for artificial pneumothorax but not treated serving as controls.	307	109	35.5	338	70	20.7

Pneumothorax treatment and disease in the contralateral lung

It will easily be understood that a better result of pneumothorax treatment is likely to be obtained when one lung only is attacked than when the contralateral lung is diseased as well. The 690 patients treated are therefore grouped to investigate this point. The results are seen in table III.

value in such cases also. In many it will be found that the contralateral lung heals up simultaneously with that under collapse. The reason is that the resisting power of the patient towards the disease is greatly improved when the pneumothorax prevents the flow into the whole body of toxins and tuberculous protein from the more diseased lung. But in a considerable number of cases the contralateral lung,

With the contralateral lung not involved 88.5 per cent 'positive results'.
With the contralateral lung involved 48.9 per cent 'positive results'.

if much diseased, will become worse as it cannot stand the strain of taking over the greatest part of the respiration, even if the pressure used in the pneumothorax is kept as low as possible.

In all cases where the x-ray examination shows a considerable amount of cavitation pneumothorax treatment should be tried, at once, if the contralateral lung is either not attacked at all or only a little attacked (examples: plates VI and VII). Should there be found cavities in both lungs it is often possible to treat the worst lung first and, when it has sufficiently improved, then to begin pneumothorax in the other side, after stopping the treatment in the first side, or continuing it simultaneously in both sides. This has been tried also in this sanatorium and with promising results, but the figures are at present too small for publication.

Pneumothorax and gold treatment

When the contralateral lung shows signs of being attacked, before pneumothorax is given or during the course of treatment, good results can in many cases be obtained by giving a gold preparation, as for instance sanocrysin, simultaneously with the pneumothorax treatment. The patients who were treated before sanocrysin was introduced, or who could not for various reasons be treated with the drug, serve as a control group. The result of this combined treatment is tabulated in table IV.

TABLE IV

Combined pneumothorax and sanocrysin treatment in patients with contralateral lung affected compared with control cases

Patients with contralateral lung attacked	Number	'POSITIVE RESULTS'	
		Number	Per cent
Sanatorium treatment with pneumothorax and sanocrysin.	139	89	64.1
Sanatorium treatment with pneumothorax, but no sanocrysin.	168	61	36.3

It will be found from a study of the table that of the patients in the group where sanocrysin was given as an auxiliary treatment, 64.1 per cent obtained 'positive results' as against 36.3 per cent in the group not treated with it. This demonstrates the great value of sanocrysin under these conditions.

A strong warning must, however, be given with regard to the use of sanocrysin in general. The drug can be very dangerous when the urine is not examined for albumin at least twice a day during the whole course of treatment. The

reason is that even the slightest nephritis will interfere with the excretion of the gold which may lead to severe symptoms of metal poisoning, if ignored. But, apart from this danger, it must be understood that sanocrysin is a dangerous drug also from its action on the tuberculous tissue itself, if given to a too advanced patient. It is just in such advanced cases, with both sides attacked, that the drug is best used in combination with pneumothorax treatment. The collapse of the more affected side will prevent the sanocrysin from acting, at one time, upon all the tuberculous foci present. Such an action would in much advanced cases bring into the circulation more tuberculous protein than the body could cope with. Preventing, by pneumothorax, the drug from acting on the more advanced lung, sanocrysin can be used with safety for the disease in the contralateral lung. To use sanocrysin in the most advanced cases without simultaneous pneumothorax treatment may have disastrous results.

Selective collapse

In connection with the question of the effect of pneumothorax treatment on the contralateral lung it should be pointed out that the whole principle of giving pneumothorax has been greatly modified during the years.

Previously the principle was to try to obtain as much collapse of the whole lung as possible, but the aim is now very different. Experience has shown that the best results are achieved when only the diseased portion of the lung is collapsed, while the healthy part of it is allowed to function, thereby relieving the strain on the contralateral lung. This collapse acting only on the diseased portion is called 'selective' (plate VII, figure 6). The name is in one way misleading as it is not the physician who selects which part to immobilize, but Nature herself. The diseased part having lost its elasticity does not expand under a low pressure which is too low to have any effect on the expansion of healthy lung tissue.

The modern principle of giving pneumothorax treatment is to insufflate just so much air as will produce the optimum effect with the minimum pressure. What this pressure is depends on so many individual factors that no general figure can be given. It has to be found in each patient by a careful study not only of the clinical symptoms but also by examination of the lungs stethoscopically and by x-rays, and by a study of the blood by various methods.

The question of adhesions

One of the most important factors with regard to the results to be obtained in a case of pneumothorax treatment is the presence or not of adhesions in the pleural cavity. Such adhesions, whether present from the beginning or developing during the treatment, will prevent the diseased part of the lung, especially that with

PLATE VI
(Photos by U. M. T. Sanatorium)

Fig. 1.—Mrs. K. Before pneumothorax; right sub-apical infiltration with large cavity.

Fig. 2.—Same patient after nine months' A P treatment. The large cavity seen much smaller close to the mediastinum in the upper part of the healed fibrotic area.

Fig. 3.—Same patient two years after discharge, with re-expanded lung; no cavity seen. Result: Clinically well; sputum, bacilli free.

Fig. 4.—Mr. P. V. Before A P. Right lung upper half affected, with large cavity.

PLATE VII
(Photos by U. M. T. Sanatorium)

Fig. 5.—Same patient after six months' pneumothorax treatment. The cavity seen close to the mediastinum.

Fig. 6.—Same patient six months later, the cavity much smaller, seen in the completely collapsed upper lobe; lower lobe expanded and functioning. A good 'selective' collapse. Result: Clinically well; sputum, bacilli free.

Fig. 7.—Mr. K. K. Before A P. Bilateral tuberculosis; whole left lung affected, with cavities; upper part right lung also affected.

Fig. 8.—Same patient after little over two years' A P; complete collapse of left lung; right fibrosed. Result: Clinically well; sputum, bacilli free.

cavities, from being collapsed. The most injurious effect of the adhesions is not that they keep the cavities open by a direct pull on the visceral pleura over them, but that they prevent the relaxation of the whole tension in the pleural cavity itself. This is a far more important factor in immobilizing the lung than the direct pressure on it by the insufflated air.

In table V are tabulated the results of pneumothorax treatment in relation to the extent of collapse of the lung as seen by x-ray examinations.

or of their liability to produce bleeding. In such cases, as well as when pneumothorax cannot be given at all, the question arises of the phrenic-evulsion operation or of thoracoplasty. In many cases these operations have the desired effect in collapsing the diseased lung with its cavities.

Effusion in the pleural cavity

Before closing it is necessary to mention the complication of effusion appearing in the pleural cavity during the treatment with pneumothorax.

TABLE V

The results of pneumothorax treatment in relation to the extent of collapse obtained

Extent of collapse of lung	POSITIVE RESULTS			DISAPPEARANCE OF FEVER			DISAPPEARANCE OF TUBERCLE BACILLI FROM SPUTUM		
				Patients with fever when artificial pneumothorax started	Of these, discharged with no fever		Patients with tubercle bacilli in sputum when artificial pneumothorax started	Of these, discharged with no tubercle bacilli in sputum	
	Total number	Positive results	Per cent						
Complete collapse	41	39	95.1	33	31	94.0	37	31	83.9
Three-fourths collapse	112	88	79.0	95	71	74.7	107	70	65.2
Less than three-fourths	141	84	59.6	124	65	52.4	139	54	38.8

It will be observed how much greater the percentage of positive results is among those patients with a complete collapse as compared with those with even a three-fourths collapse or those with less, the figures being, respectively, 95.1, 79.0, and 59.6 per cent. Similar differences of percentages are observed with regard to disappearance of fever and of tubercle bacilli from the sputum.

When adhesions are found to be present it is of the greatest importance therefore to get rid of them. Previously this was often attempted by increasing the pressure in the hope of stretching the adhesions until they snapped. Some years ago many patients suffered heroically all the disadvantages and detrimental effects of overpressure without having the adhesions broken. This method of trying to remove adhesions should never be used any more.

The only effective way of treating adhesions is by thoracoscopy with cauterization. It would carry us too far here to go into details of this treatment.

Unfortunately, it is not always possible for this treatment to be used either because of the position of the adhesions or of the size of them

An analysis of the 690 patients treated with pneumothorax reveals that effusion appeared in 54.2 per cent of the patients. From table VI it will be seen that the more advanced the cases the higher is the percentage with effusion.

TABLE VI
Pneumothorax and effusion

Stages	Number of patients treated with pneumothorax	Number of patients in whom effusion appeared	Percentage
I	3	0	..
II	50	19	38.0
III	637	355	55.7

The effect of effusion on the ultimate results of treatment is fortunately not nearly as detrimental as one is liable to think, as out of 316 cases without effusion 74.4 per cent of the patients obtained 'positive results' and out of 374 cases with effusion as many as 68.0 per cent. The difference is so small that we agree with

some other workers that the appearance of effusion is not of any real serious consequence.

It is of interest to note that the fluid appeared in 61.5 per cent of the cases within the first three months' treatment, in 18.2 per cent within the next three months, while 10.0 per cent only have fluid appearing for the first time after six months' treatment.

The question of any seasonal influence on the appearance of effusion has been investigated by us, but we do not find any evidence of seasonal influence in India worth considering.

Summary

1. The results of the treatment with pneumothorax of 1,039 patients are reviewed.

2. In the analysis are included only patients treated three months or more, and reasons for this are given. The results of treatment of 690 such patients are compared with those of 349 selected for pneumothorax, but not able to receive it on account of no free pleural space. These patients serve as a control group.

3. Nine hundred and fifty-nine out of the 1,039 patients selected for pneumothorax treatment were in III stage, 74 in II stage and 6 in I stage.

4. 'Positive results' were obtained in 71 per cent in the pneumothorax treated group while only 43 per cent in the control group. Of patients only in III stage 49.9 per cent were discharged as 'much improved' as against 26.1 per cent of those in the same stage in the control group.

5. The importance of giving pneumothorax treatment while only one lung is attacked is demonstrated by 88.5 per cent of such patients having obtained 'positive results' as against 48.9 per cent of those having the contralateral lung affected as well.

6. The value of pneumothorax treatment even in cases with both lungs involved is shown by 48.9 per cent of such patients obtaining 'positive results' as against 34.7 per cent of those in the control group, equally attacked.

7. Pneumothorax treatment should be tried in all cases showing cavities.

8. In patients with affection in the contralateral lung good results are obtained by additional treatment with sanocrysin, as shown by 64.1 per cent of patients treated with this combined treatment obtaining 'positive results' as against 36.3 who for various reasons could not have gold treatment.

9. Strong warning is given against sanocrysin treatment in advanced cases if not combined with pneumothorax treatment and reasons are stated for this.

10. 'Selective' collapse is mentioned and the modern principle of pneumothorax treatment is defined as obtaining the optimum effect

(Continued at foot of next column)

THORACOSCOPIC EXAMINATION AND CAUTERIZATION OF ADHESIONS

(INTRAPLEURAL PNEUMOLYSIS)

By P. V. BENJAMIN, M.B., B.S. (Madras), T.D.D. (Wales)
Assistant Medical Superintendent, Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle,
South India

ADHESIONS preventing sufficient collapse of the lungs are the most frequent causes of partial or complete failure in the treatment of pulmonary tuberculosis by artificial pneumothorax. It is estimated that at least 40 per cent of failures in artificial pneumothorax treatment can be attributed to this cause. Unfortunately adhesions are very often distributed over the more diseased part of the lung which is in greatest need of collapse.

In the earlier years of artificial pneumothorax treatment attempts were made to sever these adhesions by thoracotomy (by the open method). This was attended with many complications and the procedure is not now considered justifiable. In 1910 Jacobaeus introduced the present method of intrapleural pneumolysis and invented the instruments for the intrapleural division of adhesions by the closed method by galvano-cautery under the guidance of vision through a thoracoscope.

The thoracoscope is an instrument built on the principles of the cystoscope. In Jacobaeus' thoracoscope the lenses are arranged in such a way that the adhesions are seen indirectly by reflection. Others have improved on this and we have now several modifications. Kremer's thoracoscope is a direct-vision one where the

(Continued from previous column)

with the minimum pressure. This is not a constant figure but varies from person to person and is found in each individual case by a study of the clinical symptoms, by stethoscopical and x-ray examinations, and by a study of the blood by various methods.

11. The question of adhesion is investigated. Figures are given indicating the great importance of a complete collapse compared with a three-quarter collapse, and one less than this, as 'positive results' were obtained in 95.1, 79.0, and 59.6 per cent respectively amongst patients in these different classifications. Various methods of treating patients with adhesions are discussed.

12. Effusion in the pleural cavity during pneumothorax treatment is investigated. Fluid appeared amongst 54.2 per cent of the 690 patients treated with pneumothorax. The appearance of fluid is not of serious import as 68.0 per cent of those with fluid obtained 'positive results' as compared with 74.4 per cent of those without fluid.

adhesions are seen directly without any distortion. In Jacobeus' instrument, as the lens is placed on the side, a complete examination of the pleural cavity on all sides can be made easily, but, although the general view is not always so complete with Kremer's thoracoscope, this instrument gives a better orientation of the adhesions, their direction and position, and is a much easier one to work with.

In our first thoracoscopic work we used Jacobeus' thoracoscope, but we prefer for general use Kremer's.

In Jacobeus' method galvano-cautery is used for the severance of adhesions. This is found to be less efficient in controlling bleeding than the diathermy current. Hence recent modifications use the diathermy current for the coagulation and for cutting. There is still some controversy as to whether diathermy or galvano-cautery should be used. We have used both methods in our work and we are of opinion that a thoracoscopic outfit should have both available. There are certain adhesions, especially the thin string-like adhesions, where the galvano-cautery is the better. On the other hand, some broad adhesions containing blood vessels require first coagulation by diathermy.

For both the galvano-cautery and the diathermy it is useful to have different types of operating cautery electrodes. Kremer's outfit is usually equipped with straight and curved galvano-cautery electrodes. We have found Matson's flexible and jointed operating diathermy electrodes a very useful addition to the equipment for reaching adhesions difficult to reach by inflexible instruments.

Types of adhesions.—The types of adhesions preventing the collapse of the lung vary a great deal. In some patients the whole or the major part of a lobe may be adherent to the chest wall, the adhesions being very extensive, and in others the space between the chest wall and the lung may be so narrow that no cauterization is possible. Some adhesions are broad and membranous; some are cone-shaped, containing a projection of lung tissue; some are purely fibrous and band- or string-like; and some are hour-glass shaped, the outer part consisting of fibrous tissue with or without blood vessels, and the medial part consisting mainly of lung tissue.

Limitations of x-ray.—A good x-ray film or fluoroscopic examination may show some or most of the adhesions present. But it must be understood that though the x-ray gives an idea of the adhesions, yet it does not always give a true picture. In actual thoracoscopic examinations we are likely to see more adhesions than are seen in the x-ray, and the nature of the adhesions may be quite different. Flat postero-anterior films may not show adhesions that go posteriorly and anteriorly, and some adhesions which look like strings turn out to be really

broad membranous adhesions. A thoracoscopic examination alone can reveal the nature and the number of adhesions.

Indications for thoracoscopy and cauterization.—Every case treated by artificial pneumothorax in which radiological examination after the first six or eight weeks shows the lung is collapsing imperfectly is a potential case for thoracoscopy and cauterization of adhesions.

Some of the adhesions which look incauterizable at the beginning may stretch and become cauterizable in course of time. Hence it may be advantageous in some cases to wait even three or four months before cauterization is attempted. But, on the other hand, it is dangerous in some cases to wait too long. The adhesions may give way under pressure tearing open the lung underneath, causing spontaneous pneumothorax and attendant complications. In others effusion may take place and the cauterization may be more difficult.

The presence of adhesions *per se* is not always an indication for operation. Some adhesions do not prevent a satisfactory collapse. Whether a collapse is satisfactory or not can be judged by the effect of the pneumothorax on the clinical symptoms such as temperature, cough, the quantity of sputum and the presence of bacilli and also by the blood findings.

On the other hand, in some cases, although the patient improves under pneumothorax treatment in spite of the presence of adhesions, cauterization may have to be done eventually, if the adhesion shows a tendency to pull out the lung too early.

The adhesions must also be reasonably suitable for cauterization. To judge this requires considerable experience, as it is specially important to be able to recognize what is seen through the thoracoscope and to be able to say whether particular adhesions contained blood vessels or lung tissue.

Finally, there must be sufficient pneumothorax space for the manipulation of the instrument.

Contra-indications.—There are few contra-indications for the division of adhesions. If effusion is present, it has to be aspirated before cauterization. But a recent acute onset of effusion is a definite contra-indication and thoracoscopic examination should be postponed till the acute stage is over, as interference inside the pleura at this stage is likely to cause severe reactions.

Technique.—For the technique the reader is referred to one of the various books on the surgery of the thorax as it would take too much space to give it in detail here.

Complications during operation.—Serious bleeding may take place during the cauterization of the adhesions. In our experience adhesions that go towards the anterior part, *i.e.*,

towards the sternum, are more likely to bleed than those going laterally or posteriorly.

In our series we have had three cases of severe bleeding, but none of them were fatal. Two of these bleedings occurred when we used galvano-cautery before we had the diathermy outfit. In one of these it was possible to stop the bleeding by coagulation with galvano-cautery at dull-red heat. In the other, this procedure did not materially lessen the bleeding which stopped by natural coagulation after some time; about 300 c.cm. of blood were aspirated from the pleural cavity 48 hours after the operation. The patient made an uneventful recovery and was discharged 'much improved', free from bacilli.

The third case of severe bleeding occurred while using the diathermy outfit, but the bleeding was controlled immediately by touching the parietal end of the adhesion with the coagulating electrode. There have been 15 instances of mild oozing which was controlled easily by coagulation either by galvano-cautery or by diathermy. In our experience diathermy is more certain of stopping the bleeding than galvano-cautery.

Another complication that may occur during the operation is too deep coagulation, and if this extends into the lung tissue it may later cause necrosis and pleuro-pulmonary fistula. Due care in coagulation can obviate this, and in our series no such complication occurred.

If cauterization is attempted close to the mediastinum, sudden death may be caused by touching the vagus nerve; or injury by heat or by electric current may be done to the mediastinal vessels. In one of our cases the mere touching of an adhesion near the mediastinum, even without switching on the current, caused severe shock and the attempt had to be given up.

Cauterization too close to the dome of the pleura may cause injury to the sub-clavian vessels.

Another complication is that bleeding may take place from the site of the trocar puncture in the chest wall.

Complications after the operation.—Secondary bleeding may in some cases take place either from the ends of cauterized adhesions which showed no tendency to bleed at the time of cauterization or from the puncture wounds in the chest wall where the instruments were introduced. We had a secondary bleeding in one of our cases. On the third day after the operation the patient was found to be very anæmic and slightly breathless—internal bleeding was suspected and a diagnostic puncture revealed the presence of blood in the pleural cavity and 600 c.cm. of bloody fluid were aspirated. The patient got better without any other complication and we are not sure whether the bleeding came from the adhesion or from the puncture wound. The

adhesion that was cauterized in this case was a simple one and a thorough search was made for any bleeding points after the cauterization, which we do as a routine in every case, and there was no sign of bleeding whatever from the cut ends of the adhesions. The bleeding probably took place from one of the punctures in the chest wall.

The most common complication after operation is subcutaneous or subfascial emphysema. The air escapes from the pleural cavity along the track of the trocar and canula, and if the patient coughs after the operation it may spread more and more under the skin during the first 24 hours. The emphysema may extend up to the face, sometimes causing pressure on the neck and difficulty in swallowing; it may extend down to the legs. This complication has never been fatal, but it causes slight discomfort for the first 24 or 36 hours after the operation. The administration of morphia after operation to reduce excessive cough may prevent it.

Effusion may occur after thoracoscopy, but it is difficult to judge how far this is due to the operation as effusion is a very common complication in ordinary pneumothorax treatment. Of 40 cases later reviewed, three had an effusion before the thoracoscopy; in the remaining 37 effusion appeared in 19 within three months, the effusion in a number being only very small in amount. This gives a percentage of 51.2, almost the same as the general percentage for effusion in pneumothorax treated patients.

Usually the effusion appearing after thoracoscopy is serous, but it is possible for infection to be introduced by unsterile technique and by injury to the lung during operation. However in our series of cases there was no instance of infection.

Results in patients operated on in U. M. T. Sanatorium.—Since May 1932 thoracoscopic examinations and cauterization were attempted in 52 patients. In a few the cauterization was done in more than one stage. In all, 64 thoracoscopic examinations were made. The number of adhesions seen in the 52 patients was 178, but not all of them were cauterizable.

In four of the patients no cauterization could be done; in eight patients the period after operation is less than a month and they are therefore omitted; and so 40 patients are left for consideration in the following statistics:—

Among these 40, only in 10 could all the adhesions be cauterized. Collapse of the lung was increased in all these 10 after the operation; five of them were 'much improved' and two 'improved'. Tubercle bacilli were present in the sputum in all the 10 at the time of the operation, and disappeared after operation in six.

PLATE VIII

Fig. 1.—Mr. S. P. Before cauterization. Big cavity held open by adhesions.

Fig. 2.—Mr. S. P. Same patient as figure 1, after cauterization—cavity collapsed.

Fig. 3.—Mr. K. S. Before cauterization—adhesion preventing collapse of upper lobe.

Fig. 4.—Same as figure 3, after cauterization—collapse of lung good.

PLATE IX

Fig. 5.—Mr. A. Before cauterization.

Fig. 6.—Same as figure 5, after cauterization.

Fig. 7.—Mr. K. Before cauterization. Several adhesions keeping cavities uncollapsed.

Fig. 8.—Same as figure 7, after cauterization—good collapse.

In the remaining 30 patients, all adhesions that were seen could not be cauterized, but one or more adhesions were cauterized in every case. As a result of the operation, the collapse of the lung was increased in all 30. Twelve patients were 'much improved' and nine 'improved', making a total of 21 or 70 per cent positive results. Tubercle bacilli were present in all the 30 patients in this group at the time of the operation, and they disappeared from the sputum in 14 or 46.7 per cent after the operation.

TABLE I
Results of treatment

Number of patients	Much improved	Improved	Stationary	Worse
All adhesions cauterized				
10	5	2	2	1
One or more adhesions cauterized (but not all)				
30	12	9	2	7
TOTAL 40	17	11	4	8

Positive results 28 out of 40.

TABLE II
Disappearance of tubercle bacilli

Number of patients	+ T B before cauterization	- T B after cauterization
All adhesions cauterized		
10	10	6
One or more adhesions cauterized (but not all)		
30	30	14
TOTAL 40	40	20

Judged from the point of view of general improvement and from the point of view of disappearance of tubercle bacilli from the sputum, these results are encouraging and give an idea of the scope of thoracoscopy and cauterization in improving the results of artificial pneumothorax treatment in pulmonary tuberculosis.

The results of the cauterization of adhesions in four individual cases are shown in figures 1 to 8 in plates VIII and IX.

THE APPLICABILITY OF PHRENIC EVULSION IN PULMONARY TUBERCULOSIS AT THE OUT-PATIENTS' DEPARTMENT OF A CITY HOSPITAL

By A. C. UKIL, M.B., M.S.P.E. (Paris), F.S.M.F., F.N.I.
P. CHATTERJEE, M.B., F.R.C.S. (Edin.)
and

K. N. DE, B.Sc., M.B.

(From the Chest Department, Medical College Hospitals, Calcutta)

Introduction

WITH an annual mortality of 3,000 from pulmonary tuberculosis in Calcutta and a provision of approximately only 200 beds for the tuberculous in the city and suburbs of Calcutta, we were faced with the problem of rendering aid to 1,500 to 2,000 cases of pulmonary tuberculosis in this department every year. The Medical College Hospitals have only 24 beds for the treatment of pulmonary tuberculosis which were very frequently occupied with urgent cases needing hospitalization.

Being anxious to bring surgical aid to the treatment of pulmonary tuberculosis, we managed to secure the temporary beds in the emergency section of the hospital where a stay of 48 hours was allowed to each patient after either primary artificial pneumothorax (A P), phrenic evulsion or gas replacement of pleural effusion. Although handicapped in many ways, we were able to deal with 164 cases of primary A P, 2,252 A P refills, 41 cases of phrenic evulsion and 40 cases of gas replacement of pleural effusion, besides numerous cases of minor surgical procedures, in the year 1935. The number of cases is increasing so steadily that we find it difficult to deal effectively with all cases in the absence of a larger hospital accommodation. For example, out of 446 cases found suitable for admission in the indoor tuberculosis wards of this hospital only 49 cases could be admitted. Out of 143 cases which were referred to the various sanatoria, only 10 could secure admission. Besides these, it may be pointed out that 52.7 per cent of the patients seeking our aid for the first time were in stage III of the Turban-Gerhardt classification, i.e., fairly advanced cases.

Under the circumstances, we were obliged to perform phrenic evulsion in the following types of cases:—

1. PRIMARY

(a) *In unilateral cases*

- (i) Where artificial pneumothorax had failed.
- (ii) In basal lesions.
- (iii) In cases with dragging pleuro-pericardial adhesions on the left side.
- (iv) In fibroid cases with considerable displacement of the mediastinum and accompanying dyspnoea.

- (v) In cases of hæmoptysis where A P has failed and where a thoracoplasty is contra-indicated.
- (vi) In cases of dry bronchiectasis with recurrent small hæmoptysis.
- (vii) In some cases of non-productive cough with diaphragmatic pleurisy.
- (viii) In early bronchiectasis and abscess of lung in the lower lobe before induration has set in.
- (ix) In tuberculous empyema as a preliminary procedure to thoracoplasty.
- (x) When concluding pneumothorax treatment in cases where re-expansion is tardy.

(b) *In bilateral cases*

Where artificial pneumothorax was not considered to be a judicious procedure owing to more or less extensive disease, but where the reduction of lung volume and movement on the more actively diseased side was deemed likely to reduce the absorption of tuberculo-toxin and to bring about a certain degree of relaxation of pulmonary traction sufficiently well to turn the scale towards improvement.

In some cases, phrenic evulsion was done on the side contralateral to that undergoing artificial pneumothorax.

2. SECONDARY

Where the operation was done as a supplementary procedure to artificial pneumothorax, especially in cases showing adhesions interfering with effective collapse and in some cases with peri-hilar cavities where pneumothorax alone was not sufficient to bring about an effective shrinkage of cavities owing to the contiguity of the lesion to the resistant root of the lung. It has also been done in some cases before concluding artificial pneumothorax, especially in cases where a thick pleura interfered with re-expansion of the lung. In some of the latter, compressive oleothorax was done as a final procedure where the patient could not stay in town or where the lung tried to expand, while still showing a certain amount of activity in the affected area of the lung.

In a few cases with upper lobe lesions, scalenotomy was also performed in addition to phrenic evulsion.

A few points about the operation

We do not propose to describe the whole technique of the operation, but a few points about it may not be out of place here. The operation itself is simple and can be performed easily under local anæsthesia, except in young children in whom we have used evipan-sodium injections (intravenous) with success.

The researches of Felix and Goetze (1922) in Sauerbruch's clinic showed that simple division of the nerve was inadequate, as in 20 to 30 per cent of cases an important accessory branch joined the nerve below the usual level of section. There are several accessory branches but

the most common runs with the nerve to the subclavius and 3 cm. lateral to the phrenic, and has to be divided if the diaphragm is to be truly paralysed. This nerve arises from the fifth cervical nerve in the neck, enters the thorax in front of the subclavian vein and joins the main cord immediately below the sterno-clavicular articulation. At least 4 to 5 inches of the phrenic nerve should, therefore, be evulsed to make one feel reasonably certain that connections with the accessory phrenic nerve have been broken.

During the dissection of the nerve no pain is experienced by the patient. Clamping before division and traction on the nerve causes pain. The intensity of the pain is variable and, we believe, depends on two factors, (1) the amount of adhesions to be torn through and (2) the temperament of the patient. It is, however, by no means unbearable. During traction, there is always an acceleration of the heart beat.

The dissection became more difficult in our series when the pad of fat overlying the scalenus anticus muscle was excessive or where big veins or adherent enlarged lymphatic glands and lymphatics had to be dissected out.

The situation of the nerve is by no means constant. Usually it is situated on the scalenus anticus muscle and runs across its middle, downwards and inwards. This position may vary and the nerve may run along the inner edge of the muscle, at times covered by the sheath of the carotid artery or along its outer edge. In our series, the nerve was seen to run along the inner margin in 40 and along the outer border in 22 instances. The difficulties in finding the nerve, however, are more when it arises from the brachial plexus or arises from a common trunk with the nerve to the subclavius, i.e., when they arise from behind the scalenus anticus. In this series, the nerve was found to arise in 5 cases from the brachial plexus and in 2 cases from the common trunk with the nerve to the subclavius.

It is not always easy to take out the whole nerve. The size of the nerve varies considerably and, at times, is so thin that it cannot stand the amount of traction necessary to pull out the whole length. Chronic inflammation around the nerve may interfere with its elasticity and make it friable. If the nerve is bound down by dense adhesions not only does the patient complain of pain but it has a chance of breaking above the level of adhesion. During traction, slight oozing of blood occurs around the nerve at the inlet of the thorax. If the oozing is more than usual and blood is seen to well up it has become necessary at times to cut the nerve at the lowest point exposed.

Complications, such as division of the vagus, sympathetic and branches of the brachial plexuses and tearing of the subclavian vein or even of portions of the infected lung, are fortunately rare. In our series, there were

fortunately no untoward operative complications. In one case, there was a moderate amount of hæmoptysis which lasted for four days, while in a few there was a slight elevation of temperature which usually lasted for four or five days after the operation. In some cases of bilateral disease, the temperature lasted for a longer time, owing perhaps to an activation of foci in the other lung. In a few cases, dyspnœa disappearing in a few days after the operation was noticed. Mild gastric and intestinal disturbances, such as borborygmi and flatulence, nausea and vomiting, appeared in some cases but they disappeared in three to five days. These were commoner in left-sided cases. Some of the right-sided cases complained of pain in the lower part of the chest and right hypochondrium for a few days after operation.

Rise of the diaphragm and length of nerve removed

The rise of the diaphragm was not immediate. It takes months after the operation to reach its utmost limit. In the cases observed by us, the extent of average ascent was 3.75 cm. at the end of three weeks and 6.25 cm. at the end of two months. In two cases of removal of the whole nerve the hemidiaphragm was seen to reach up to the level of the third rib, yielding excellent results.

Many observers are of opinion that it is the positive intra-abdominal pressure which causes the elevation of the paralysed diaphragm and that, if the whole nerve is removed, the hemidiaphragm, by gradual atrophy of the muscle fibres, can be expected to rise high up. But this does not take place in cases where there are dense and extensive lateral adhesions. The degree of rise of the diaphragm is influenced by the nature of the lung changes and is greatest, other factors being equal, where the disease is of the chronic productive type with extensive fibrous-tissue changes.

The minimum rise in our series was noted to be 2.5 cm. and the maximum 9 cm. The average rise of diaphragm on the right side was found to be 3.5 cm., while that on the left side was 4 cm. It has been noticed that the rise of the diaphragm is higher and quicker on the left than on the right side. The following table gives some of the details:—

Rise of the diaphragm in relation to the length of nerve removed

Length of nerve removed	Number of cases	Average rise of diaphragm	
		Right	Left
Less than 12.5 cm. ..	110	3.5 cm.	4 cm.
More than 12.5 cm. but not the whole nerve.	60	4.5 cm.	5 cm.
The whole nerve ..	30	8.0 cm.	9 cm.

A brief analysis of the cases

We are dealing with 200 cases of phrenic evulsion, of which 198 were of pulmonary tuberculosis and two of lung abscess. The two cases of lung abscess had involvement of the lower lobe and both were benefited by the operation.

Primary phrenic evulsion, *i.e.*, where it was done as the sole surgical procedure, was done in 112 cases, and secondary phrenic evulsion, *i.e.*, where it was done as an adjunct to artificial pneumothorax or as a preliminary to thoracoplasty, was done in 86 cases. In one case of bilateral involvement, artificial pneumothorax was done on the left side and phrenic evulsion was done on the right with beneficial results. Of the total number of cases, four were operated on in 1932, 36 in 1933, 50 in 1934, 62 in 1935 and 48 in 1936, which means that all the cases have not yet passed the time test in assessing the results.

Age and sex distribution

Of the total number of cases 155 were males and 45 females. One of the female cases was pregnant at the time of operation which was followed by good after-results. The details of age and sex distribution are shown in the following table:—

Age	Male	Female
9-10 years	1	Nil
10-15 "	2	Nil
15-20 "	32	10
20-30 "	84	22
30-40 "	32	12
40-50 "	4	1
TOTAL ..	155	45

Classification according to stage of disease

According to Turban-Gerhardt classification, 18 cases were in stage II and 180 cases in stage III at the time of operation. None of the cases were in state I.

Localization of lesion

The following table shows the extent of lung involvement on both sides according to regions:—

Extent of involvement	SITE OF DISEASE		TOTAL
	Right lung	Left lung	
Chiefly limited to the upper zone.	58	22	80
Limited to the middle zone.	7	3	10
Limited to the lower zone.	10	4	14
Bilateral disease with more extensive lesion on the side indicated.	57	37	94
TOTAL ..	132	66	198

It will be noticed that, in the present series of cases, lesions on the right side were twice as frequent as those on the left side. Of the total number of cases, 112 showed the presence of single or multiple cavities (usually thin-walled) distributed as follows:—

In the lower zone	..	10 cases.
" " middle "	..	38 "
" " upper "	..	64 "

EFFECTS OF THE OPERATION ON THE DISEASE PROCESS

1. *On cough and expectoration.*—If cough is due to diaphragmatic irritation and expectoration is prevented by a tonic contraction of the diaphragm, the cough is relieved and expectoration facilitated by phrenic evulsion. Expectoration is gradually diminished along with a clinical improvement of the case. The sputum was markedly diminished, after the operation, in 76 and moderately diminished in 32 of our cases; the remainder showing no effect. This information, in outdoor cases, had naturally to be gathered from the statements of the patients and hence we do not consider it as of unimpeachable accuracy.

2. *On tubercle bacilli (TB) in sputum.*—Out of 198 cases, 178 had TB-positive sputum at the time of operation. The 20 negative-sputum cases never became positive during the period of observation. Of the 178 positive-sputum cases, 98 (or 55 per cent) became negative as a result of phrenic evulsion, while 80 still remained positive.

3. *On cavities.*—Cavities may be thin-walled, thick-walled or moth-eaten. It is well known now that thin-walled cavities are a predominant feature of subacute or chronic pulmonary tuberculosis in this country owing to comparative scarcity of urban and industrial areas and a consequent low degree of tuberculization of the population as compared with highly industrialized and urbanized countries in the West. A majority of our cases had thin-walled cavities.

Cavities could be demarcated in 112 cases and their localization was as follows:—

Localization	Number of cases	No. showing shrinkage and fibrosis	Percentage
Upper zone	64	54	84.3
Middle "	38	36	94.7
Lower "	10	10	100.0

A complete obliteration of cavities was noticed in 42 cases (= 37 per cent). Cavities were appreciably shrunk in 58 cases (= 52 per cent), and no results were discernible in 12 cases (= 11 per cent).

As will appear from the above table, of 64 upper lobe cavity cases, 54 showed diminution in size and fibrosis, showing that upper-lobe

lesions need not constitute a contra-indication to phrenic evulsion. O'Brien's (1930) (*Journ. Amer. Med. Assoc.*, xcv, p. 650) figures in this connection will be found interesting. Among 311 cases of cavity in the upper lung field in his series 46.6 per cent were closed, in 40 cases of cavity in the middle lung field 62 per cent were closed and in 27 cases with cavity in the lower lung field 80 per cent were closed.

4. *Other effects.*—It has already been mentioned that symptoms such as cough and expectoration are greatly relieved. Symptoms such as pain or dragging due to diaphragmatic adhesions are also greatly relieved. Owing to the diminution or obliteration of cavities and of the lymph and venous stasis, there is diminished absorption of tubercle toxins and a consequent reduction of pyrexia and improvement in general health. The sedimentation rate of blood is also correspondingly lessened.

It should be well understood that phrenic evulsion is but an accessory to general sanatorium regime, coupled or not with other measures such as gold therapy, artificial pneumothorax, etc. We have employed it in those cases where from the nature of lung changes or from the social status and general condition of the patient we desired to overcome those mechanical changes which appeared to us to act as a hindrance or barrier to healing. Those patients who listened strictly to our instructions regarding regulation of rest and exercise naturally did better than the foolish ones who took the law into their own hands and thought that they could disregard our instructions after the operation has been done.

Results in relation to the rise of the dome of the diaphragm

The degree of improvement depends, to some extent, on the length of the nerve removed—the greater the length of nerve removed, the better the improvement, as will appear from the following table in our series:—

Length of nerve removed	Number of cases	Clinically improved	Percentage
Less than 12.5 cm.	110	50	45.4
More than 12.5 cm. but not the whole nerve.	60	45	75.0
The whole nerve	30	25	83.3

Morrison Davies (1933) (*Pulmonary Tuberculosis*, p. 323) is of the opinion that the diminution in the volume of the lung which follows as a result of hemidiaphragmatic paralysis is manifested in some cases as strikingly on the apical as on the basal lesions. There is some divergence of opinion on this point but our findings lend support to his views. Unless the root of the lung is firmly fixed by

adhesions, the movements of the diaphragm affect the apex almost as much as the base. The collapse of the lung, consequent on the paralysis of the hemidiaphragm, is probably equally distributed throughout the whole lung, although the effects are more noticeable in those parts which show more proliferative lesions or where there are basal adhesions.

The results given below in relation to localization of lesions in our series will lend support to the views of Morrison Davies and others :—

We cite below three typical cases for illustration :—

Case I.—A. H., Mohammedan, male, aged 30 years, tailor, came under our observation on 29th June, 1932.

History.—Wife died of pulmonary tuberculosis. He has been suffering from cough for five months and fever and wasting for one month before he sought treatment here.

Physical examination.—Comparative loss of resonance and medium crepitant râles over both subclavicular areas, but more extensive over the left. Skiagraph taken on 18th July, 1932, showed semi-productive infiltration and cavitation of both upper lobes in the

Results in relation to localization of lesions

Extent of involvement	Arrested	Much improved	Improved	Stationary	Worse	Died	Total	Percentage of positive results
Limited to upper zone	1	1	20	27	14	17	80	27.5
Limited to middle zone	0	2	0	0	2	6	10	20.0
Limited to lower zone	1	8	4	1	2	0	16	81.2
Bilateral disease, with more extensive disease on the side operated upon.	0	11	72	0	2	9	94	88.2
TOTAL ..	2	22	96	28	20	32	200	..

We should like to state that all the operations have not been done in the same year. We introduced the operation in our out-patient's clinic in the year 1932. As will appear from the following table, as many as 110 cases were operated on during the last two years. Many of these cases have swelled the figures under the category of 'improved cases', especially in the bilateral ones. With further 'time control' some of them will shift their categories to the better or worse side. The assessment of results according to the period of observation will be seen better in the following table :—

sub-clavicular area, but more active on the left side (plate X). There were no extra-pulmonary complications. Sputum was TB-positive (in large numbers).

Treatment.—Artificial pneumothorax was tried on the left side but failed. Left phrenic evulsion was, therefore, done on 12th August, 1932, 20 cm. of the nerve being removed. Sputum has remained TB-negative since 5th December, 1932. He has gained 32 lb. in weight since then and has remained symptom-free. Is doing full work (tailoring) for the last two years. Has had two courses of gold therapy (intramuscular solganal B. oleosum).

Case II.—M. M. R., Hindu, male, aged 26 years.

Previous history.—Pleurisy left, six years ago.

Hæmoptysis in streaks, a year ago.

Year in which operation was done	1932	1933	1934	1935	1936	TOTAL
Period of observation with results ..	5 years	4 years	3 years	2 years	1 year	..
Arrested	1	1	0	0	0	2
Much improved	1	8	6	5	2	22
Improved	1	4	28	35	28	96
Stationary	0	3	8	5	10	28
Worse	0	8	5	5	4	20
Died	1	12	3	12	4	32
TOTAL ..	4	36	50	62	48	200

It will be seen that 'positive' results (i.e., improvement) have been obtained in 60 per cent of cases. If we leave aside the cases for 1935 and 1936, it will be seen that 50 out of 90 cases (or 55 per cent) showed improvement and are still living. If we take the cases operated on during the first three years, we shall find that at least 20 per cent of the persons operated on have regained their working capacity.

Complaints.—Cough, with half an ounce of expectoration in 24 hours—for four months, a low fever for two months and a moderate amount of wasting.

Physical examination.—Comparative loss of resonance over the left upper lobe of lung. Cavernous breathing and medium crepitant râles over the same area. Deficient air entry in right upper lobe. Sputum showed a large number of TB in smear. Skiagraph showed extensive semi-productive infiltration with a cavity in the middle zone (plate X).

Treatment adopted.—Artificial pneumothorax having failed on the left side, phrenic evulsion was done on 26th June, 1936, and the entire nerve (31 cm.) was removed. Since then the patient has gained 36½ lb. in weight within six months, the sputum has remained TB-negative since 16th July, 1936, and the case has remained symptom-free. A course of solganal B. oleosum has also been given. There is no extra-pulmonary complication.

Case III.—Dr. D. M., Hindu, male, aged 40 years, medical practitioner, Calcutta.

History.—Diabetes and high blood-sugar detected in 1928. Came to the senior author on 7th January, 1936, for progressive loss of weight for two years, slight cough, repeated moderate hæmoptysis and the fever off and on since 1934.

Physical examination.—The patient was running a slight temperature at the time and the maximum daily pulse rate was 100 per min. Expectoration—four teaspoonfuls daily, containing a fair number of tubercle bacilli. Chest examination showed some loss of resonance, increase of vocal fremitus and presence of occasional râles. Skiagraph of the chest showed a 'circular focus' in the medial portion of the right upper lobe and semi-productive infiltration of the whole of the left lung with a good-size cavity in the left sub-apical area.

Treatment undertaken.—Glycosuria was controlled with insulin therapy. Artificial pneumothorax was tried on the left side but failed. Left phrenic evulsion was done on 27th January, 1936, six inches of the nerve being removed. The temperature came down to normal a fortnight after the operation and he has been fever-free since. He has had two courses of solganal B. oleosum. He was examined last on 20th February, 1937. He has gained 2 stones 2 lb. since operation and has a pulse rate of 70 to 76 per minute. The left hemidiaphragm has risen to 3rd rib above, the infiltrations are fibrosing well, the old cavity has nearly been obliterated and the sputum has remained negative since June 1936 (see figure below).

areas, in whom localization of lesions in the lung is rather fragmentary owing to generally marked hypersensitiveness to tuberculo-toxin, as has already been stated.

Barely 10 per cent of the cases are found to be suitable for artificial pneumothorax therapy. Among them also, various degrees of ineffective compression of lung are obtained owing either to the presence of adhesions or to the proliferative nature of the changes. Among the latter, where cauterization of adhesions is not possible and where thoracoplasty is not indicated or possible, we have to choose our cases for phrenicectomy. Besides these, we have to think of this procedure where artificial pneumothorax has failed or where, from the extensive distribution of lesions, no other surgical procedure is applicable. Where pneumothorax is practicable and effective, the question of phrenic evulsion does not arise, nor does it arise when there are multiple and thick-walled cavities or when the lesions are acute and exudative. Whether phrenic evulsion is the sole surgical procedure or is used as an adjunct to pneumothorax, the cases have got to be properly chosen. The fact that it is a simple operation which is not likely to give rise to shock or serious reaction, that it has to be done only once, that it brings about the same sclerotic changes in involved lung tissues as in pneumothorax, that it can be performed on patients who are in a grave condition, and that it is free from the risks of reaction and

Case III.—Phrenic evulsion in a diabetic, resorbing infiltrations and obliterating the vomica in the left upper lobe.

Discussion

We have already stated that over 50 per cent of the patients who seek the aid of this section of the hospital are found to be in a fairly advanced stage of the disease. A fair number of patients comes from rural and semi-rural

pleural effusion common in pneumothorax, no doubt makes a great appeal for its application in suitable cases. The paralysis of the hemidiaphragm gives an additional amount of rest

(Continued at foot of opposite page)

Case I. Fig. 1.—Lesions when patient first came under observation (18th July, 1932).

Case I. Fig. 2.—Same patient 3½ years after left phrenic evulsion. It will be seen that after the correction of the toxic imbalance by the left-sided operation, the lesions on both sides began to improve.

Case II. Fig. 1.—Lesions one month after left phrenic evulsion.

Case II. Fig. 2.—Same case six months after operation. The infiltration in the left upper and middle zones has considerably cleared up and the cavity in the middle zone practically closed.

PLATE XI

Case 1.—Replacement oleothorax.
Dated 24th July, 1934.

Case 2.—Compressive oleothorax.
Dated 22nd November, 1934.

Case 3. Fig. 1.—Dated 15th June, 1933. Exudative infiltration in right upper lobe and peri-hilar region. Cavity in right sub-apical area. Sputum TB-positive.

Case 3. Fig. 2.—Dated 14th December, 1934. After pleural effusion has cleared up and before phrenic evulsion. Infiltrations much harder, upper lobe cavity nearly obliterated.

OLEOTHORAX IN THE TREATMENT OF PLEURO-PULMONARY TUBERCULOSIS

By A. C. UKIL, M.D., M.S.P.E. (Paris), F.S.M.F., F.N.I.
and

K. N. DE, B.Sc., M.B.

(From the Department of Chest Diseases, Medical College Hospitals, Calcutta)

By the term 'oleothorax' is meant the introduction of massive quantities of oil (plain or antiseptic) into the pleural cavity for therapeutic purposes. This branch of phthisiology is indebted to Bernou (1922) for introducing and developing the method. A large amount of work has now been done on the subject in France, Switzerland, Germany, England and other countries. The method, however, requires a careful judgment in the selection of cases, a far greater technical skill in application and a closer observation of cases than pneumothorax therapy. Hence, like all new methods of therapy, it has been subjected to some divergence of opinion among different workers.

A case of uninterrupted and successful pneumothorax treatment requires a period of three years or more to bring about healing of the lesion. Unfortunately certain difficulties and complications are encountered during

(Continued from previous page)

to the affected lung by diminishing the respiratory excursion, by increased compression and by relaxation of lung when cavities are held open by adhesions to chest wall.

In apical lesions, we have now begun to perform scalenotomy, in combination with phrenicectomy, in suitable cases but are not yet in a position to assess its results. As the scalene muscles are accessory muscles of respiration, the operation is expected to relax the apical region of the lung and to reduce the size of cavities.

Phrenicectomy has a definite place in the treatment of pulmonary tuberculosis, particularly in the type of case we had to deal with. We do not subscribe to the view that phrenic evulsion should be done as an adjuvant in every case of pneumothorax where there is cavitation. It is better to judge each case on its own merits. Remembering that 91 per cent of our cases were in stage III and the remainder (9 per cent) in stage II of the disease before the operation and that, in the absence of sanatorium or hospital beds, we could offer them no other treatment, we have reason to be gratified to find that 55 per cent of the patients became TB-negative in the sputum and that 60 per cent of the total showed 'positive' results. Even extra-pulmonary lesions, like laryngeal tuberculosis, have been seen to improve after the control of the TB in the sputum brought about by phrenic evulsion.

the course of treatment. The introduction of aseptic or antiseptic oils into the pleural cavity has been devised to mitigate or solve some of them. It is in no sense a substitute for pneumothorax treatment.

For example, in some cases of pneumothorax, especially where selective collapse has been obtained, the healthy part of the lung may tend to expand too quickly and form 'riding' adhesions with parietal pleural membrane and gradually obliterate the pneumothorax space. In these cases, the introduction of aseptic oil into the pleural cavity checks the re-expansion and consequent adhesions by virtue of its slow absorption and weight and thus allows effective pneumothorax to be carried on. This is called *inhibition pneumothorax* (= *oleothorax anti-symphysaire* of French authors).

In some cases where a pleural effusion has occurred, the tendency to adhere becomes more marked and the pleura becomes thicker and more rigid. Air inflations are not always enough to maintain an effective collapse in such cases. In these cases, the introduction of oil into the pleural cavity lessens the permeability of the pleural membrane and secures a better compression of the affected area of the lung and, owing to its slow absorption, obviates the necessity of frequent refills. In certain cases with rigid-wall cavities, air insufflations are inadequate to effect a closure of the cavities. In some of these cases, the replacement of air by oil serves the purpose. This type of oleothorax is called *compression oleothorax*. In a smaller number of cases, the mediastinum shows insufficient rigidity and does not allow the introduction of enough air for pneumothorax without producing a mediastinal hernia. In these cases, the introduction of oil stimulates slight reactions and thickens the mediastinal pleura. In some cases a patient may be unable to continue the air insufflations at the required intervals. Here oleothorax may be substituted for pneumothorax very carefully. Oleothorax has sometimes been employed to close small transitory, intermittent or valve-type perforations, where the viscosity and pressure of the oil, aided by a thickening of the pleura at the mouth of the fistula, effect a closure of the opening. The addition of a small percentage of antiseptic serves to inhibit or relieve a complicating pyothorax later on. It is contra-indicated for pleuro-pulmonary fistulae with a large opening. In all the above types of cases, oleothorax exercises both a mechanical and rigidifying action.

By far the largest use of oleothorax is in the treatment of chronic tuberculous pleurisies, sero-fibrinous or purulent, which may occur primarily or in the course of pneumothorax treatment. It has been noted that 30 per cent of pulmonary tuberculosis cases give a previous history of pleurisy and that 80 per cent of chronic pleural effusion are of tuberculous

origin. In a series of 130 pleural effusions examined microscopically, by culture and animal inoculation, according to the technique described by us in a previous paper (Ukil and Thakurta, 1936), tubercle bacilli could be demonstrated in direct smear (without concentration) in 14 cases, by culture in 18 cases and by animal inoculation in 22 cases. If we exclude 28 materials from tuberculous empyema cases, 19 or 18.6 per cent serofibrous effusions showed tubercle bacilli. 78.5 per cent of the empyema cases showed tubercle bacilli on examination by one or more of these methods. Gloyne's (1913) figures with regard to serous effusions were much higher than in our series. He found tubercle bacilli by microscopic examination in 40 per cent of serous and in 71.43 per cent of purulent effusions. The discrepancy with regard to serous effusions is due to the fact that our figures relate to an examination of direct smears without any digestion and concentration method being used, whereas Gloyne used them besides making smears from the teased clot. It is well known that 40 to 50 per cent of pneumothorax cases develop fluid at some time or other during the course of treatment. The small effusions disappear in several weeks with diuretics and calcium chloride. In the larger effusions which have lasted for three or four months, the albumin content, specific gravity and cellular elements begin to increase and show a more frequent presence of tubercle bacilli. Aspiration and administration of diuretics answer the purpose in a fair number of cases. Where, however, the exudate fails to resorb owing to alteration in the permeability of the pleura, or shows symptoms of toxæmia and seriously affects the well-being of the patient, or where the fluid gradually becomes turbid and purulent owing to caseous tuberculous pleuritis or to pulmonary perforations, the question of replacement of the effusion by antiseptic oil has to be considered in order to disinfect the pleural cavity, to prevent re-formation of fluid and to maintain the pulmonary collapse, if necessary. Among 265 cases of artificial pneumothorax under the care of Dumarest and Brette (1929), pleural effusions occurred in 186 cases, 42 of which turned out to be purulent. In pneumothorax cases, complicated with such effusions, two questions have to be faced—(1) preventing obliteration of the pleural cavity, and (2) combating the intrapleural infection. In these cases, if we can stop re-formation of the exudate, we may be able to avoid the much more severe operation of thoracoplasty in unilateral cases. If the purulent exudates are allowed to pursue their natural course without treatment, a majority of the cases tends to end by perforation or amyloid changes. Duboff (1919) reported 20 cases in 1919, ten of which had ruptures either into the bronchus or through the chest wall, while a number of the rest

developed amyloid changes. In these cases, if we can stop re-formation of the exudate, we may be able not only to prevent these accidents but to avoid the much more severe operation of thoracoplasty (in unilateral cases). The addition of an antiseptic to the oil for oleothorax is a much more important question in these cases. This type of oleothorax is known as *disinfection oleothorax*.

To prevent these complications, various attempts have been made to find out an agent which would admit of easy application, would prevent pleural symphysis, would not cause undue irritation of the pleura or produce a systemic effect, would possess a bacteriolytic or bacteriostatic effect on the tubercle bacillus and even secondary organisms, and would preferably liquify the debris present in the exudate. As a base, two types of oil have been used, paraffin oil and olive oil of the highest degree of purity and neutral in reaction. An antiseptic may be added to them in various proportions to serve different purposes. As antiseptics, various substances have been tried, such as alepol, acriflavine, metaphen (4 nitro-anhydro-hydroxy-mercuri-ortho-cresol), iodipin and gomenol. We have almost exclusively used gomenol in our work. Gomenol (niaouli oil), a volatile oil obtained by distillation of the leaves of *Melaleuca viridiflora* growing abundantly in the region of Gomen in New Caledonia, has been more extensively used than any other agent. The toxicity and bactericidal properties of this oil and its vapour have been carefully studied by Clerc and others. It has been shown that gomenol possesses a marked influence in inhibiting the growth of many organisms, particularly of the acid-fast group, but is not so marked towards other organisms, except in high concentrations. Gomenol lessens the permeability of the pleura and thereby lessens the absorption of toxins from effusions and of air in pneumothorax. Dilutions are made in olive oil in strengths varying from 1 to 10 per cent according to the purpose for which it is employed. It is supplied by Laboratoire du Gomenol, 48, Rue des Petites-Ecuries, Paris, and the local agents in India are G. Loucatos, 15-A, Elphinstone Circle, Bombay. Rudman and Ellison (1932) consider metaphen-in-oil to be superior to gomenol in its bactericidal and liquifying properties and in reducing the specific gravity of pleural exudates.

Gomenol dissolves with difficulty in paraffin oil but does so with ease in olive oil. Paraffin oil is absorbed more slowly than olive oil. Olive oil is supposed to keep the pleura soft, while paraffin oil thickens it. Olive oil is saponified in contact with pus and leads to increased absorption, thereby exercising a nutritive value. It is more lethal to tubercle bacilli than liquid paraffin. Paraffin oil floats on the surface of the pleural effusion. Paraffin oil is sterilized by heating for 20 minutes at 160°C.

and olive oil at 105°C. for one and a half hours. Gomenol is usually mixed with paraffin oil in strengths varying from 0.5 to 2.0 per cent and with olive oil in strengths varying from 2 to 10 per cent and then allowed to stand for two to three weeks to allow the oils to be thoroughly mixed together. We have often used plain paraffin oil, without any antiseptics, in inhibition and compression oleothorax with good results.

Inhibition and compression oleothorax

In *inhibition oleothorax* a complete blockage is not necessary and hence a comparatively small amount of oil serves the purpose. In *compression oleothorax* a complete blockage is desirable. In cases where there are dense adhesions over a thin-walled cavity, oleothorax should be done with great caution, avoiding high pressures altogether, as it is dangerous to stretch the pleural cavity in the presence of adhesions. In these cases the object is to secure better compression where air insufflations have been unable to achieve sufficient collapse. In one of our cases it was necessary to replace pneumothorax by the introduction of oil, owing to the patient's inconvenience about air refills (case 1). Really speaking, this is not an example of compression pneumothorax; it might be called *replacement oleothorax*. We have used paraffin oil, instead of olive oil, in these cases, as it is less absorbable and because it thickens the pleura. We have successfully employed this, without the addition of an antiseptic (1 to 2 per cent gomenol) as has been advocated by some workers. But in case of laxity of the mediastinum we prefer to add a little antiseptic (1 to 2 per cent gomenol) in order to bring on pleural reaction with a view to stiffening the membrane. In these cases, small quantities should be introduced and the patient should be instructed to lie on the opposite side to allow the oil to bathe the mediastinum.

The technique of oil injections is the same as described below under disinfection oleothorax, i.e., the pleural sensibility is first tested with small doses at weekly intervals and, if no intolerance is observed, larger injections not exceeding a total of 250 c.cm. in the female and 350 to 400 c.cm. in the male are given, keeping the various difficulties and danger points in view, and not forgetting to release a corresponding volume of air with the help of the water manometer.

The patient is placed recumbent in the dorso-lateral position lying on the healthy side. A small cushion is placed under the axilla to bring about a bulging of the chest. The oil should be warmed and introduced, with strict aseptic precautions, at the highest point of bulging. The A P needle is introduced at the highest point of the air pocket and the air pressure gauged, from time to time, during the process.

A Dieulafoy syringe with rubber connections is more convenient but the procedure can be managed with a 20-c.cm. syringe attached through rubber to an A P needle. Needles for the introduction of paraffin oil should have a bore of 1.0 mm. In this case, air, in units of 20 c.cm., may be withdrawn and the corresponding amount of oil introduced carefully. We have also employed 50-c.cm. and 100-c.cm. syringes for this purpose. The pressure of the oil can be determined by noting whether oil comes out of the opening of the needle. If it overflows, it indicates positive pressure; if it remains stationary at the mouth of the needle, the pressure may be considered as neutral; if it does not reach the mouth of the needle, the pressure is probably negative. The force necessary to push the piston down with the fingers also gives us an indication of the pressure.

The final pressure should either be neutral or slightly negative. Too high positive pressures are not advisable as they are likely to tear away adhesions and cause serious displacement of a mobile mediastinum or may bring about trouble if an effusion occurs. According to indications, the pneumothorax cavity is to be incompletely or completely filled up with oil, leaving a few cubic centimetres of lipiodol to facilitate periodical observations under the x-ray screen. A careful watch should be kept about the occurrence of effusions and the patient should be screened once a fortnight in the beginning. The paraffin oil floats on the top and the layer can be differentiated by careful examination under the x-ray screen. The pressure may be determined by putting in a needle once a month during the first three months and thereafter every three months. As a certain amount of oil (50 to 100 c.cm. of oil per month according to Fontaine) is absorbed, although the absorptive capacity of the pleura gradually decreases, oil replacement should be done when necessary. Puncturing at the most dependent part will enable us to see whether an effusion has occurred.

Results.—Out of 22 cases of oleothorax in our series, inhibition oleothorax was done in two, replacement oleothorax in one and compressive oleothorax in five. All these cases had a favourable termination, five being 'arrested' and three 'much improved'. Maston, Ray W. (1932), obtained, in a series of 50 cases, satisfactory results in 50 per cent of the cases. In 40 per cent of these, the treatment had to be abandoned owing to persistent exudate formation, and in another 10 per cent owing to the appearance of severe constitutional symptoms. In our series no such drawbacks were noticed.

We cite below one case of replacement oleothorax and two cases of compression oleothorax for illustration:—

Case 1.—R. J., a Hindu male, aged 20 years, came to us in December 1932 for fever, cough and emaciation lasting for three months. Sputum was tubercle

bacilli positive. On examination, the right upper lobe was seen to have exudative infiltration with small cavities.

Treatment.—Artificial pneumothorax was done on the right side but after some time effusion occurred. After aspiration of the serous fluid, the right lung was expanding too quickly and obliterative pleurisy was apprehended. At this time he wanted to go to his native village. We introduced 250 c.cm. of sterile paraffin oil into the pleural cavity and observed the case for a few weeks (plate XI). Finding that no further effusion had taken place, he was allowed to go home and to report himself back later on. He is now doing his usual work for one year without any symptom.

Case 2.—S. R. L., a Hindu male, aged 21 years, came under our care in July 1933 with a history of fever, cough and emaciation for one year, and periodical moderate hæmoptysis. The sputum was tubercle bacilli positive.

The whole of the right lung was involved with rather productive infiltration and three cavities in the upper and middle lobes with considerable retraction of the trachea. The left upper lobe also had an area of productive infiltration with a small vomica in the centre.

Treatment.—In view of the tracheal retraction and superficial position of the cavities, we performed phrenic evulsion on 29th July, 1933, when five inches of the nerve could be taken out. This had a beneficial effect, but to supplement it we tried to perform pneumothorax on account of the adhesions above; only a moderate-size air pocket could be created. Since this required frequent refills we decided to perform an oil blockage of the pocket with aseptic paraffin oil. This helped not only to render the sputum negative and to close the cavities, but also caused the disappearance of the lesions on the left side (plate XI).

Case 3.—A. F., a European female, aged 23 years, was diagnosed in June 1933 as a case of pulmonary tuberculosis with exudative infiltration in the right upper lobe and perihilar region and a cavity in the sub-apical area (plate XI, figure 1). Sputum was tubercle bacilli positive.

She underwent artificial pneumothorax treatment at K. E. Sanatorium at Bhowali for 18 months, where she had a course of solganal B. oleosum. Effusion occurred during pneumothorax treatment, the visceral pleura was thickened and adhesions formed at the right costo-phrenic angle (plate XI, figure 2). Tubercle bacilli disappeared from the sputum for some time but subsequently re-appeared, probably from the perihilar lesion, as by this time the cavity in the upper lobe appeared to have nearly closed and the infiltrations hardened.

Treatment.—Right phrenic evulsion was done in January 1935. By the 1st March, the diaphragm had risen by one inch (plate XII, figure 3). As the patient wanted to go away, compressive oleothorax was done with aseptic paraffin oil. The sputum became tubercle bacilli negative and the patient remained well since then.

Disinfection oleothorax in pleural effusions

In the acute stage of pleural effusion, the pleura being already acutely inflamed and irritable, oleothorax is not applicable for fear of further irritation of the pleural surface. If the liquid is serous or sero-fibrinous and if it continues to form and cause mediastinal displacement and dyspnoea, a simple aspiration, if necessary by gas replacement, serves the purpose. In a majority of cases, a single aspiration stops further effusion.

In some cases, the temperature remains high even after withdrawal of effusion of the above description and the fluid continues to re-form. The fluid gradually gets turbid and the patient loses ground. In other cases, a low degree of fever persists for weeks, although fluid may not

form so quickly as in the former case. In both these types of cases, the removal of fluid and its replacement by gomenolized oil of low strength stop further formation of fluid and reduce the toxæmia. This action is believed to be brought about by the diminished absorption of toxins owing to thickening of the pleural membranes and also to the dissolution of bacilli-laden tissues, floating in the fluid by the proteolytic ferments released by the dissolution of leucocytes. The improvement after oleothorax becomes evident by the disappearance of fever and the improvement of appetite and the general condition of the patient.

If, in some of the above cases, repeated aspirations are done without oleothorax, the character of the fluid gradually changes from turbid to puriform, so that finally a cold abscess in the pleura is produced. Tuberculous empyema (1) may complicate an artificial pneumothorax, or (2) a spontaneous pneumothorax, or (3) may be due to rupture or puncture of a subpleural focus, or to rupture or division of pleural adhesions, or, rarely, (4) may arise without any apparent tuberculous lesions of the lungs.

Clinically, a case may be slow in evolution and non-toxic, where the inflammatory process subsides and the temperature falls to normal after a few aspirations, or acute, toxic and virulent, which is normally associated with extensive involvement of the pleura with acute tubercles or with secondary infection, high fever of hectic type and profound toxæmia. In the former type of cases, oleothorax produces very good results. In the latter type, oleothorax does no harm and may spare him the necessity of a surgical operation like pleurotomy or thoracoplasty. Apart from disinfection of the pleural fluid, oleothorax helps to prevent the approximation of pleural surfaces and to improve the general condition of the patient by reducing toxæmia. In many cases, such a marked improvement takes place that a major operation like thoracoplasty is not needed.

The choice of a method of treatment will depend on whether the underlying pulmonary parenchyma is diseased or not and the empyema is due to tubercle bacilli alone or in association with secondary organisms. If the underlying lung parenchyma is apparently healthy, our aim should be to obliterate the pleural cavity by allowing it to expand. If there is accompanying involvement, especially cavitation of the underlying tissues, we should aim at keeping the lung collapsed.

In simple tuberculous empyema without apparent lung lesion we should evacuate the pus as completely as possible by gas replacement where indicated and replace by oil. The results are good where the whole pleural surface is bathed with oil. If the pus is thick, one might have to thin it with Gauvain's solution or with chloramine-T or with pepsin solution.

Case 3. Fig. 3.—Dated 1st March, 1935. One and a half months after right phrenic evulsion—diaphragm one inch higher. Compressive oleothorax being carried on.

Case 4. Fig. 1.—Dated 20th July, 1934. Productive but active infiltration and cavitation in left upper lobe. Collapse interfered with by adhesions. Tuberculous empyema.

Case 4.—Fig. 2.—Dated 22nd November, 1935. Same case after oleothorax treatment. Infiltrations mostly resorbed and fibrosed. Empyema inspissated and lung expanded.

Case 5.—Dated 2nd February, 1937. Appearance of parenchyma and empyema cavity (partly filled with oil) 14 months after commencement of oleothorax therapy. The dark appearance is due to thickened pleura.

PLATE XIII

Case 6. Fig. 1.—Dated 24th April, 1936. Empyema left, lung lesion in left sub-apical area still active. Patient losing ground. A small cavity in left sub-apical area is indicated by an arrow.

Case 6. Fig. 2.—Dated 2nd February, 1937. As a result of oleothorax, the exudation of pus has stopped, the patient has considerably improved and joined work.

Case 7.—Dated 22nd December, 1936. Left tuberculous empyema improved by oleothorax and finished with thoracoplasty.

Case 8.—Dated 30th August, 1932. Pus formation stopped, but spontaneous pneumothorax took place—oil removed to relieve pressure.

If the character of the pus does not change or if there is prompt re-formation of the fluid, we have tried to destroy tubercle bacilli by introducing 5 to 20 c.cm. of 2 per cent methylene blue in absolute alcohol in gradually increasing doses at weekly intervals, as too frequent introduction may cause a bloody effusion.

If secondary infection is present and if oleothorax fails, a closed intercostal drainage and irrigation (with 0.1 per cent gentian violet solution) might improve the condition, if there is no bronchial fistula. If there is a large bronchial fistula, rib resection and open drainage may be done, to be followed by thoracoplasty. In a case of simple tuberculous empyema with lung lesion, we should maintain the collapse by pneumothorax and oleothorax or with oleothorax alone where the lung lesions are found to be active. The quantity of oil to be introduced and its frequency depend on whether a superficial cavity is present in lung parenchyma or not, as in the former case there is danger in introducing much oil at a time for fear of exerting too much pressure and producing spontaneous pneumothorax. If oleothorax fails, thoracoplasty with or without preliminary phrenic evulsion has to be done. In some cases, intercostal drainage and lavage might help in improving the condition of the patient and rendering him fit for thoracoplasty. The worst prognosis has to be given for such of these cases where secondary organisms infect the empyema.

Technique

Olive oil seems to us to possess several advantages over paraffin oil as a vehicle for gomenol in disinfection oleothorax, as explained earlier in the paper. The preparation of gomenolized oil having been done as previously described, we have to test the sensitiveness of the pleura, which varies differently in different cases. The irritability of the pleura is expressed by increased exudation inside the pleural cavity and by constitutional signs like fever, chills, pain, etc., nausea, vomiting and prostration. It is not wise to re-introduce oil before the reactions have completely subsided. Sometimes the contact of the oil itself reduces the irritability of the pleural membrane. The oil should be at a temperature between 100°F. and 105°F., which can be had by placing the oil flask in hot water and by warming the syringe before use.

The effusion or pus is withdrawn as completely as possible with gas replacement where necessary and 5 to 10 c.cm. of 2 per cent gomenolized olive oil is introduced into the pleural cavity. If there is no febrile reaction within a week, 10 to 20 c.cm. of 5 per cent oleogomenol are introduced. At the end of two weeks, the patient is examined under *x*-rays (with the patient lying down on his side to indicate the presence and nature of adhesions) and, if no fresh fluid formation has taken place, 50

to 100 c.cm. of 5 per cent oleogomenol are introduced, after ascertaining that the pressure in the pleural cavity before inducing oleothorax was frankly negative (never plus or zero, as a cavity may communicate with the pleural space). If there is no temperature, introduce 200 to 300 c.cm. of 5 per cent oleogomenol after a fortnight. If a temperature reaction is noticed after the introduction of oleogomenol, suspect fresh fluid exudation and examine by *x*-rays.

The needle for the introduction of olive oil should have a bore of 0.7 mm. and should be short. The danger of using needles of wider bore is that oil and pus may leak and leave a pleuro-cutaneous fistula or a cold abscess under the skin. To avoid these, we penetrate the muscular layers a little beyond the skin puncture. An additional precautionary measure is to introduce a few drops of iodine inside the puncture track after withdrawal of the needle. The puncture point of the needle for the withdrawal of pus should be in the lowest part of the mid-axillary line, so as not to disturb the posterior region of chest for a future thoracoplasty, and the patient should sit up and lean slightly forwards to ensure as complete an evacuation as possible. After withdrawal of the pus, the patient is made to lie in the dorso-lateral position and the oil is introduced through a puncture in the anterior axillary line about the level of nipple, to avoid leakage of pus and infection of the needle track. A syringe with a 4-way stop-cock is a great convenience in operative technique in these cases, but we have used, at various times, a Dieulafoy 2-way syringe, a transfusion syringe, and 20-100 c.cm. Record syringes connected to an A P needle through rubber tubing.

The skin has to be carefully sterilized with tincture of iodine and alcohol, the proposed track is then infiltrated with novocaine solution and the oil needle introduced. After the preliminary evacuation of pus, air in the pleural cavity is to be gradually released as oil is introduced. The amount of oil introduced should be about half to two-thirds the quantity of pus evacuated. The final pressure, estimated through water manometer, should not exceed zero, as a rule. It is important to leave a slightly negative pressure above the oil. The presence of the oil, however, is much more important to gauge, in order to prevent serious mediastinal displacement. Bernou uses an oleo-manometer for this purpose which is a bit cumbersome. A rough and easy method of estimating it is by withdrawing the syringe, while it is still full of oil, keeping the needle *in situ*. If the oil overflows, it indicates positive pressure. The needle can also be connected with an empty glass syringe (without piston), when, if increased pressure is present, the oil will be seen to rise into the syringe. In order to get a uniform idea, it is necessary to use a needle of the same calibre on each occasion.

If the pus is thick or if the empyema is of a virulent or toxic type, the pleural cavity should first be completely emptied of pus, then washed out with warm physiological saline and, lastly, oleo-gomenol introduced. The immediate result in these cases is a fall in temperature, but, if it rises again, the same method of aspiration, irrigation and oil replacement should be repeated until the temperature falls. After the temperature remains normal, irrigations are not needed and the oil bath of the pleura suffices.

Complications.—Apart from pleural sensibility or reactions which may occur in some cases, perforation of visceral pleura may occur, due probably to the re-activation of tuberculous foci lying under the pleural surface. Small perforations may be intermittent; gomenol-oleothorax may help to close them. Even if it does not close the perforation, it may prevent complications and may help to prepare the patient for thoracoplasty. Patent perforations can be verified by instilling a few c.cm. of a 1 per cent solution of methylene blue in saline when the coloured fluid is expectorated. If it occurs after oleothorax has been done, the usual signs are some pain and displacement of mediastinum and the escape of gomenol fumes into the bronchi and the expectoration of the oil. If this occurs, the oil must at once be withdrawn and the effusion, if any occurs, should be periodically withdrawn to prevent the level of the exudate reaching the perforation point and thus escaping into the bronchi. In these cases, thoracoplasty has to be advised.

Other complications which may arise in the course of treatment are pleuro-cutaneous fistulæ and threatened empyema necessitatis.

Results

Tuberculous empyema, under conservative treatment, has a gloomy outlook. The outlook has improved considerably with the adoption of major and minor surgery.

We had to deal with 14 cases of tuberculous empyema, in whom oleothorax treatment was adopted, four without lung lesions and 10 with lung lesions. In the former group, two recovered and two died. Of the two deaths, one had spontaneous pneumothorax (case 8 in our series) and the other was a case of virulent or toxic effusion. Of the 10 cases with lung lesion, three died and seven have shown marked improvement. Of the three deaths, two died of bilateral disease and one died of spontaneous pneumothorax. Of the seven cases in which improvement is recorded, two required subsequent thoracoplasty (case 7 is one of them), two have not required this operation (case 4 is one of them) and three have considerably improved but may require thoracoplasty later on (cases 5 and 6 are among them).

Matson (1932) in his series of 50 cases, treated in the course of seven years and observed for a minimum period of three years,

obtained satisfactory results (i.e., empyema cleared up and the collapse was maintained by air or oil) in 60 per cent of cases. In the remaining 40 per cent, failure was due to pleuro-pulmonary and pleuro-cutaneous fistulæ, and failure of disinfection or re-formation of pleural exudate. Fontaine's (1929) and Marie's (1929) figures are almost identical.

Remarks

Oleothorax, if the cases are carefully chosen and the treatment is properly conducted, has been shown to be a valuable adjunct to collapse-therapy in pulmonary tuberculosis and to the treatment of tuberculous pleural effusions. The method has been and can be applied to cases attending the outdoor department of a well-conducted hospital. The results obtained by us compare favourably with those obtained in Europe and America.

Case 4.—Mrs. N. B. D., a Hindu female, aged 22 years, had pleurisy on the left side in 1930. She was at the Madanapalle Sanatorium for a year (1933-34) for the treatment of tuberculosis of the left lung, where she was treated with artificial pneumothorax and sanocrysin therapy. She developed an effusion and was discharged as clinically cured. When she came to us on 23rd March, 1934, we found active but fibrosing lesions in the left upper and middle zone and an empyema reaching up to the level of the second rib (plate XII, figure 1). She complained of a slight cough but no fever. The maximum daily oral temperature was, however, found to be 99°F. and pulse rate 90 per minute.

Treatment.—The pus was withdrawn and disinfective oleothorax was done four times in the course of one and a half years. In between oleothorax she received 2 to 10 c.c. of 2 per cent methylene blue in absolute alcohol into the empyema cavity. The present condition is seen in the skiagram (plate XII, figure 2). The patient is doing a moderate amount of work. In view of the improvement obtained, thoracoplasty was not necessary.

Case 5.—R. N. A., a Hindu male, aged 27 years, was undergoing artificial pneumothorax for infiltration in the right upper lobe at the Lucknow Medical College, since 1934, and had an effusion three months before he came under our care on 7th January, 1935. He had a slight cough and fever with a maximum daily rise of temperature 100°F. for three months.

The patient was moderately wasted, pale and toxic. The right lung was fairly collapsed and the pleural cavity contained a purulent effusion up to the level of the fifth rib.

Sputum was tubercle bacilli negative, but the effusion was positive.

Treatment.—Pus was aspirated five times and was replaced by oleo-gomenol. The pus became gradually thinner and ultimately disappeared after 14 months (plate XII). The lung lesion showed good fibrosis. The patient regained weight considerably, became afebrile and resumed his duties. As the right lung was failing to expand, he was advised thoracoplasty one year ago, but the patient has not been able to make up his mind yet.

Case 6.—B. N. C., a Hindu male, underwent artificial pneumothorax at Jadavpur Tuberculosis Hospital for infiltration and cavitation in the left sub-apical area for eight months from July 1935, during which time he developed pleural effusion (plate XIII, figure 1). He was discharged in March 1936 and came under our care, when we found tuberculous empyema up to the second rib. The patient was having temperature and losing weight.

THORACOPLASTY IN PULMONARY AND PLEURAL TUBERCULOSIS

By P. V. BENJAMIN, M.B., B.S. (Madras), T.D.D. (Wales)
Assistant Medical Superintendent, Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle, South India

Historical survey

THORACOPLASTY as an operation for pulmonary tuberculosis is being increasingly used with encouraging results in modern tuberculosis institutions. In the latter part of last century there developed two methods of trying to secure a closure and consequent healing of cavities both

(Continued from previous page)

Treatment.—Gomenol-oleothorax was done on three occasions, after aspiration of pus. The pus formation seems to be stopped now, the patient has been afebrile for three months after the first aspiration and has joined his work. The infiltration in the lung parenchyma has cleared up (plate XIII, figure 2). The patient is being watched.

Case 7.—B. K. N., a Hindu male, aged 32 years, first came to us in 1932, with a history of low evening fever and cough for two months. Skiagram of the chest showed exudative infiltration and cavitation in the left upper lobe. The sputum was tubercle bacilli negative.

The patient went away and had artificial pneumothorax treatment in different sanatoria. He came back to us towards the end of 1934 with pleural effusion which was found to be tuberculous empyema.

Treatment.—The pus was aspirated several times and replaced by oleo-gomenol. The formation of pus was thereby greatly checked but as the patient was not making steady improvement, he was advised thoracoplasty. Left phrenic evulsion was done as a preliminary step. Thoracoplasty was done in two stages towards the end of 1935 (plate XIII). Since then the patient improved considerably and became free from all symptoms.

Case 8.—A. K. G., a Hindu male, aged 25 years, came in May 1932 with tuberculous empyema of the right side, low fever and emaciation. Between May and August 1932, pus was aspirated four times and replaced by oleo-gomenol, commencing with 2 per cent and gradually increased to 10 per cent. Pus formation stopped and the patient improved and went home. He came back after a couple of weeks with spontaneous pneumothorax and died in hospital (plate XIII).

based on the same principle. One of these methods was that of artificial pneumothorax introduced by Forlanini. The other started with the assumption that it is largely the rigidity of the chest wall which prevents the walls of a cavity from collapsing where fibrous tissue tends to retract the lung.

Quincke (1888) therefore proposed that the ribs over the affected lung should be mobilized by resection to give free play to the natural process of healing by retraction. Two years later Karl Spengler adopted this method in dealing with cases complicated with pleural effusion, but by 1903 he had developed the operation now known as extra-pleural thoracoplasty. Still the results of these earlier operations were very imperfect and uncertain. It was Brauer followed by Friedrich (1907) who advocated extensive rib resection. They reasoned that a collapse approximating to that obtained by artificial pneumothorax must be achieved before it could be hoped to obtain the same results. Although the theory was right, the operation was attended by a very high mortality and it was only between 1911 and 1913 that Wilms and Sauerbruch developed the technique of the present-day thoracoplasty—'extra-pleural paravertebral thoracoplasty'. The principle of this operation is the removal of the posterior ends of the ribs as far back as the transverse processes of the vertebrae. The removal of comparatively small segments of the posterior ends of the ribs gives greater collapse of the lung than the removal of larger segments of the anterior or lateral portions. At the same time it was recognized that it was essential that part of the first rib should also be removed, as this greatly influences the collapse.

Since that time the operation has gained popularity all over the world.

Selection of cases for thoracoplasty

In all cases where surgical intervention is indicated, artificial pneumothorax is the method of choice, as it produces a better collapse, if adhesions are not present; it is of less strain to the patient and it can be stopped at will, if the other lung gets worse.

If pneumothorax fails, owing to the presence of adhesions, the ideal case for thoracoplasty is one with a unilateral lung affection of a chronic proliferative type in a patient whose general condition is comparatively good. Such cases usually have cavities and a tendency to retraction of the lung seen by the falling in of the ribs and by the dragging of the mediastinum towards the affected side. These signs show that Nature is attempting to deal with the disease, but unfortunately Nature's attempts frequently fall far short of what is required. Immobilization of the ribs over the affected area helps this natural process.

Among Indian patients, however, such ideal cases are rarely seen. The disease is not often

unilateral and instead of the chronic fibrotic type are found more frequently the acute or semi-acute exudative types. But experience has shown that good results can be obtained by thoracoplasty in many of these cases, although not ideal; for many of them no other procedure is known which can offer hope of improvement.

In the selection of these cases and in the decision as to the type and extent of the operation, the utmost co-operation is required between the physician and the surgeon. The best would be that the surgeon and the physician be the same individual, but this is not always possible. The physician is in a better position to understand the various problems connected with tuberculosis, especially the question of allergic and focal reactions and the immuno-biological factors which vary from time to time even in the same individual, and in planning the operation the surgeon has to take into consideration the results of this individual study of the patient by the physician. Following a standardized technique described in textbooks without this individual study is bound to lead to failure. This is recognized as a necessity by all chest surgeons in the West and it is even more necessary in India where we have to deal with non-ideal cases.

It has to be emphasized in this connection that it is of the utmost importance for the patient to be treated on sanatorium lines after the operation. The operation is only a help to supplement the natural healing process which is best achieved under sanatorium regime.

Contra-indications

The most important contra-indication to thoracoplasty is, of course, widespread contralateral affection. Extensive emphysema, bronchitis or asthma or any other condition which seriously reduces the vital capacity; myocarditis, serious kidney disease or advanced tuberculous enteritis are all contra-indications. Wasting may be present, but not extreme cachexia. Patients over 45 years of age do not stand the operation well.

The extent of rib resection required

In the earlier years of the operation the rule was always to do a total thoracoplasty either in one or several stages, even if there was only an upper lobe affection. But the modern tendency is to confine the collapse of the lung as much as possible to the diseased areas and to leave the healthy parts to function normally. In the majority of cases as the disease is confined to the upper and middle zones, a partial upper thoracoplasty is all that is required. This modern technique of localized thoracoplasty has even made it possible to do a bilateral thoracoplasty when the disease is confined to the upper lobes of both lungs.

In earlier years also a preliminary lower thoracoplasty, and in some cases a phrenic

evulsion, was done with the idea of preventing an extension of the disease to the lower healthy part of the lung by secretions from the collapsed upper part after operation. The danger of such an extension, however, is not a very real one, and these preliminary operations are now considered unnecessary and may even be harmful when the lower lobe is free from the disease. But when the lower lobe is affected a complete thoracoplasty is essential, even if the upper lobe is free.

Occasionally, when the cavities are very large a posterior thoracoplasty may not be enough to secure a complete collapse. Then a supplementary anterior thoracoplasty or in some cases a supplementary extra-pleural pneumolysis may be required.

Stages of the operation

The number of stages in which the thoracoplasty operation is to be done is still a matter of controversy. But this is mainly when a complete thoracoplasty is done in patients with a unilateral chronic affection such as is found in European patients.

In Indian patients, where the disease is more acute with the possibility of severe allergic reaction following the operation, tending to spread the disease, our experience has shown that there is not much doubt that a complete thoracoplasty in one stage is exposing the patient to an unnecessary danger. Even a partial thoracoplasty in some patients may have to be done in two stages, removing only three or four ribs at a time.

Thoracoplasty in tuberculous empyema

There are certain types of tuberculous empyema either produced by a pulmo-pleural fistula or developed as a complication in artificial pneumothorax treatment where the closed method of aspiration and drainage even with negative pressure suction apparatus may not allow the lung to expand and obliterate the pleural cavity. It is well known that in old-standing cases of empyema the visceral pleura gets so thick that it is difficult or impossible to expand the underlying lung. In such cases complete thoracoplasty is often necessary to bring the parietal and visceral pleura into apposition that they may become adherent. Here the operation is a much more severe one than in ordinary lung tuberculosis as a complete removal of all the ribs, and not only the posterior ends but the anterior ends also, may be necessary. The operation may have to be done in several stages. In some cases the pleura may not become adherent even with these extensive rib resections, and it may be necessary in such cases to remove the parietal pleura and stitch the muscles directly over the visceral pleura or allow the wound to heal by granulation from the bottom.

Review of cases operated on in U. M. T. Sanatorium, Arogyavaram

Since November 1932, 26 thoracoplasty operations in 17 patients have been performed at this sanatorium. In 14 of the patients the operation was done for pulmonary tuberculosis, and in three for tuberculous empyema.

In 13 of the 14 patients operated on for pulmonary tuberculosis, the operation was an upper posterior paravertebral thoracoplasty. In these cases from 5 to 8 ribs were removed in one stage, except in one patient; 7 ribs being the maximum removed in one stage.

The results of these cases are as follows:—

TABLE

Operations	Much improved	Improved	Worse	Died
13	7	2	1	3

It will be seen that 9 out of 13 of these patients obtained positive results, and of these 7 were 'much improved'. All the 13 patients had tubercle bacilli in the sputum at the time of operation and in 6 the bacilli disappeared in one to three months after.

There was no immediate operative mortality in the 26 thoracoplasty operations. Of the three patients who died, one died four days after the operation of acute dilatation of the stomach; another died on the 11th day most probably because of a general dissemination of the disease; the third death occurred about a year after the operation.

In one case a full antero-lateral thoracoplasty was done because the patient was too weak to stand the more severe posterior thoracoplasty. The operation was done in two

stages, the anterior ends of ribs 1 to 5 being removed in the first stage and the lateral segments of ribs 6 to 10 in the second stage. The patient has improved considerably, but bacilli are still present in the sputum (four months after the operation) and collapse of the lung is not marked. It may ultimately be necessary to do a posterior thoracoplasty.

The three cases in which thoracoplasty was done for tuberculous empyema have all improved. One patient is alive and well, nearly two years after the operation. The other two are still under treatment, six months and two months after the operation, and both have improved much.

Illustrative case notes

(1) Mrs. F. G., aged 30; admitted 15th September, 1931. Left side extensively affected, with large cavity about three inches in diameter in infra-clavicular region. Temperature on admission 100°F. to 100.6°F.; tubercle bacilli present in sputum. Artificial pneumothorax attempted on 25th September, 1931, but failed; phrenic evulsion on 3rd October, 1931, because lower lobe was also affected. Two courses of sanocrysin given. Lung improved, cavity shrunk to two inches diameter, but sputum still positive. On 24th November, 1932, upper posterior thoracoplasty, ribs 1 to 7 being removed. Patient discharged 'much improved' on 17th April, 1933, and is still alive and well over three and a half years later (plate XIV, figures 1 to 3).

(2) K. J., male, aged 23; admitted 19th June, 1933, from another sanatorium where he had been since 1930 and had had artificial pneumothorax, 25 injections and phrenic evulsion. Admitted here for thoracoplasty. Patient had extensive affection on left side with large cavity in upper zone; pleura thickened; vocal chords ulcerated. Fever 100°F. to 101°F. Sputum tubercle bacilli positive. On 25th July, 1933, left upper thoracoplasty; ribs 1 to 6 removed. Within one month patient had no fever and no bacilli were found in the sputum. Discharged 26th February, 1934, as 'much improved' and is still keeping well and working as a teacher, nearly three years later (plates XIV and XV, figures 4 and 5, and text-figures 6, 7 and 8).

THE TREATMENT OF CERVICAL GLANDULAR TUBERCULOSIS

By F. M. COLLINS, M.chir. (Camb.), F.R.C.S.
MAJOR, I.M.S.

District Medical Officer, The Nilgiris, Ootacamund

GLANDULAR tuberculosis is probably the commonest manifestation of surgical tuberculosis in this country, and the cervical glands are those most frequently affected. The infecting organism enters the body sometimes through intact mucous membrane, but most often through some obviously diseased focus in the mouth—carious teeth, tonsils or adenoids. While the human tubercle bacillus may gain entry from dust or dried sputum, the bovine bacillus derived from infected milk is often the cause: in either case the bacilli pass along the lymphatics and settle in the glands which act as filters protecting the blood stream, especially if these glands are already, or have been recently, diseased.

(Continued from previous page)

(3) Mrs. E. F., aged 39; admitted 7th July, 1933, with high fever, very toxæmic. Found to have spontaneous pneumothorax on left, with empyema. This was treated by frequent aspiration and washing out by closed method and gomenol-oleothorax. Later, on sinus forming, a permanent open drainage introduced and frequent washing continued. The temperature was lower and general condition improved, but sinus persisted and there was no sign of lung expanding and obliterating pleural cavity. On 10th December, 1934, first stage of complete thoracoplasty, ribs 1 to 5 posterior ends removed; 23rd January, 1935, second stage, ribs 6 to 7 posterior ends removed; 22nd February, 1935, third stage, whole of 8th and 9th ribs and anterior ends of ribs 5 to 7 removed. Patient improved steadily, empyema cavity closed and sinus healed. Patient discharged on 15th March, 1936, as 'much improved' and is still alive and well (plate XV, figures 9 to 11).

Summary

(1) A short historical survey is given of the development of the thoracoplasty operation.

(2) In dealing with selection of cases for thoracoplasty it is pointed out that the ideal unilateral cases of the West are rarely found in India, but yet good results can be obtained in selected non-ideal cases.

(3) Emphasis is placed on the necessity of the utmost co-operation between the physician and surgeon in planning the operation.

(4) The main contra-indications to the operation are given.

(5) The nature and extent of the operation and the number of stages required with reference to Indian patients are discussed.

(6) The scope of thoracoplasty in tuberculous empyema is described.

(7) Results are given of 26 thoracoplasty operations in 17 patients. Out of 14 patients operated on for pulmonary tuberculosis, 10 obtained positive results, and in 6 out of 14 tubercle bacilli disappeared from the sputum; three patients in whom thoracoplasty was done for empyema have all obtained positive results.

The infected glands pass clinically through stages from uniform soft enlargement at first discrete, soon becoming matted by peradenitis, to caseation, softening, liquefaction, involvement by the tuberculous process in turn of fascia, muscle and skin, secondary staphylococcal infection, abscess formation (often the typical 'collar-stud' abscess), rupture, sinus formation, and tuberculous involvement of the skin.

The pathological changes are most marked at the centre of the lesion, in the glands earliest affected, where caseation and liquefaction may be evident, while the peripheral glands, infected by retrograde lymph flow and not clinically evident, show merely enlargement and microscopic tubercles. The process may be arrested at any stage with shrinkage and calcification, the latter an event much less common in the neck than in the mesentery or mediastinum. More frequently unfavourable and untreated cases reach the final stages of sinus, scarring and scrofuloderma with the ever-present risk of general dissemination.

The diagnosis is seldom difficult though in theory the whole gamut of swellings of the neck should be passed in mental review. The patient is a young adult in fair health, the mass is of considerable size, matted, nodular, of uneven consistence, without a definite edge, with or without fixation to the fascia and skin. Often both sides are involved, though unequally: the axillary gland may be enlarged, and probably there are no other manifestation of tuberculosis. The upper anterior vertical glands are usually primarily and most extensively affected: less frequently other groups, *e.g.*, upper posterior, or lower, or submaxillary, are the main seat of the disease. In practice two conditions only give rise to doubt: sub-acute or chronic non-specific inflammatory adenitis that occurs with, or is residual to, sepsis in the mouth and lymphadenoma: here, the glands are smaller, harder, of more uniform size and consistence, the spleen may be enlarged, the blood picture may show a secondary anaemia and there may be characteristic bouts of periodic fever of the Pel-Ebstein type. A pseudo-adenomatous type of disease is recognized, where the glands are unusually nodular and project markedly beneath the skin, and tuberculosis has been described as a late complicating lesion in the glands of Hodgkin's disease. Though painless in the early stages until pyogenic infection has ensued, tuberculous cervical adenitis forms an obvious unsightly mass in the neck, so that even in a country where the disease is notoriously late in reaching the surgeon, cases are generally seen at a stage when they should be amenable to treatment, and the problem arises as to what line of attack is best adopted in eradicating the trouble.

The source of infection being bacilli in the milk and their portal of entry some focus in the

mouth, the first step is the elimination of these two factors. Prophylaxis along these two lines has made tuberculous cervical adenitis, once a common complaint among the poor of the large towns in England, a comparatively rare disease in 1936.

Provision of tubercle-free milk is a matter for public health legislation, but boiling or better pasteurization of children's milk, with provision of the requisite vitamins destroyed in the process, is a simple precaution. Removal of tonsils (by enucleation, not by the guillotine) and adenoids, and treatment of dental caries are minor surgical procedures. 'Tonsils before glands' should be a routine procedure, the only possible disadvantage being that (as has happened in some cases of my own) the patient, frightened by the temporary discomfort of the tonsillectomy, may refuse further active treatment.

As in tuberculosis, generally, what is known as 'hygienic' measures is the essential part of treatment: were it possible, every case of tuberculosis, including glandular tuberculosis, would be treated in a sanatorium, or at least along sanatorium lines: unfortunately, in India we are very far from the stage where sanatorium beds are available for every case requiring accommodation. Moreover, it is my experience that not a few of the poorer and more ignorant people here lack the patience and perhaps too the confidence to persevere in a line of treatment the results of which are necessarily, and inevitably, slow: so often having at last abandoned unsuccessful lines of native medication, they expect something dramatic or even miraculous when at last they entrust themselves to the more orthodox 'systems'. It is essential that the case be removed from insanitary surroundings, especially from contact with other tuberculous lesions (e.g., a case of phthisis in the same house), that adequate fresh food be provided, especially tubercle-free milk, butter, eggs, fruit and vegetables with plenty of vitamins, and that sunlight, fresh air and healthy occupation, with exercise, be adequate. Drug treatment must play only a subsidiary part and there is no specific.

In the early soft discrete stage iodides in the shape of syrupus ferri iodidi are effective: cod-liver oil and calcium should also be given as in tuberculosis generally. In later cases with periaadenitis and softening, prolonged courses of tuberculin may do much good though results comparable to those obtained in genito-urinary tuberculosis are not usual. Radiotherapy in any form is seldom likely to be available: the value of radium or deep x-ray is doubtful, and, if unsuccessful, subsequent operation is certainly more difficult from the fibrosis that ensues. Artificial sunlight is hardly necessary in a country where natural sunlight is seldom lacking, but graduated general radiation of the whole body may act as a tonic in cases where

it is not possible to obtain adequate sunlight: local radiation to the neck is of value and my impression is that it constitutes a valuable post-operative measure.

There can be no disagreement as to the paramount importance of 'hygienic' treatment. Controversy arises as to how the glands themselves should be dealt with. Physicians point to the impossibility of removal of all the diseased glands which in practice, they say, never occurs. Recurrence is almost inevitable, sinus formation common after operation, cosmetic results poor, and atrophy and paralysis of muscles from nerve injury frequent; as it undoubtedly is, but naturally varies inversely with the experience of the surgeon. They urge that surgery should be confined to the aspiration or incision of abscesses, contending that in this way sinus formation and scrofuloderma are at least no more frequent than following radical operation. On the other hand, surgeons hold that medical treatment is uncertain, slow and time-consuming, entailing regular attendance at a clinic for treatment and observation, with absence from school or work. They give equal importance by 'hygienic' measures, and regard operation as one stage only in the treatment as a whole: they point out that the surgery of tuberculosis does not pretend to aim at the complete eradication of the disease: rather the main bulk of the trouble is removed and the rest left to nature. They do hold however that the actual glands are more expeditiously and radically treated by a clean operation which aims at entire extirpation of the local disease, and as their experience increases they fear less the failures of recurrence and sinus formation. The results are best in the early case before softening and liquefaction is extensive: the failures of medical treatment are naturally less favourable. Though the problem is a perennial one, in Europe there has undoubtedly been a swing of the pendulum in favour of medical treatment, but it must be remembered that prophylaxis has greatly lessened the incidence there, and tuberculous relief, ensuring regular attendance at well-organized clinics, facilitates continuity of treatment. In India these factors do not prevail, and it is my contention that while hygienic treatment, approximating as nearly as possible to sanatorium conditions, is carried out as thoroughly as possible, operation is more likely to lead to a successful result than a purely medical regime. My particular object in this paper is to urge the case for early operation and perhaps to give some help to surgeons in remote stations where surgical amenities are not too good, and to encourage them to deal radically with these cases.

Two types of disease are definitely not amenable to operation: those rare cases of generalized infection of most of the gland groups in the body, and those cases where the lower deep

cervical glands are solely or primarily involved: here the infection has spread from a pulmonary or pleural focus, often showing signs of activity. Involvement of the lower group, secondary to the upper group, is no contra-indication. Surgery, though it may be only a phase in the medical regime, is imperative when the glands have passed the mobile uncomplicated stage. Abscess should be aspirated and emptied using an oblique approach without the injection of sclerosing emulsions. If the abscess rapidly re-fills and especially if a culture of the aspirated pus shows a secondary staphylococcal infection, it is wiser to incise and perhaps curette the walls, while the overlying tissues are still healthy, rather than to attempt repeated aspiration which is more likely to lead to a sinus along the needle track. The radical operation is one of some magnitude, and the operator must be prepared to make a clean sweep of every gland from the clavicle to the base of the skull. If possible the mass of glands is removed in one piece, but the operator must go carefully over the wound to see that not even the smallest gland remains. The extent of infection is notoriously greater at operation than is apparent clinically. When both upper and lower groups are involved, it may be right and generally wiser to do a two-stage operation through separate incisions. Both sides of the neck should not be operated on at one sitting.

Ability to perform this operation pre-supposes acquaintance with the anatomy of the neck. A sufficiently accurate idea of the position of the cervical glands is possible if they are considered as lying in two sets: a vertical set—the deep cervical glands divisible into upper and lower, anterior and posterior groups—and a horizontal set—the submaxillary and submental glands. The superficial glands which lie on, and not below, the deep cervical fascia (mastoid, pre-auricular, occipital, etc.) are seldom the seat of tuberculous disease, and, even if they are, are small, discrete and easily removable. The descriptive anatomy of the textbooks, of which it is out of place to speak here, is likely to be disappointingly inadequate in this operation: most of the well-described structures are not seen at all, and the importance of the fascial planes and of veins is out of proportion to their textbook prominence. Venous hæmorrhage, especially with unsatisfactory anæsthesia, is very troublesome. The operator must learn to know the appearance, if not the name, of a vein, whether distended or collapsed, and the ability to enter the right layer of fascia makes all the difference between an easy and tedious operation. Really good light and a competent assistant are two further essentials.

Anæsthesia is a matter in which the operator in India will have little choice: ether or ether-chloroform mixture given off a mask is perfectly satisfactory, though intra-tracheal gas-oxygen-ether is better, having the great

advantage of removing the anæsthetist and his apparatus from the operation field. If one end of a towel is folded to three or four thicknesses and the thickened edge fixed along the angle of the jaw with towel clips, and the free end then turned back over the anæsthetist's hand supporting the jaw and holding the mask, satisfactory exclusion of the operation field is secured. I have seen some brilliant neck dissections under local infiltration but would not recommend this method to a surgeon who operates on only a few cases every year.

The incision is transverse in the skin folds of the neck and extensive over the most prominent part of the tumour, wherever this lies. Sinuses and unhealthy skin are excised in the transverse incisions. Two parallel transverse incisions are better than any vertical extension. Three or four skin scratches at right angles to the proposed incision are made, so as to secure accurate coaptation of the flaps, which are apt to slide sideways with the head turned to one side and extended over a sand bag. The transverse incision must have been unknown a generation ago, as one all too frequently sees adults with conspicuous stretched scars resulting from incisions parallel to the sternomastoid. The wound is very accurately closed in layers with a continuous stitch uniting the platysma, followed by an intradermic skin suture: this with practice takes little longer than any other, and is always worth while when the resulting linear scar is considered. The incision is carried through skin and platysma, and wide flaps are turned upwards and downwards well clear off the glandular mass in every direction: the flaps should be as thick as possible and protected with tetracloths and hot towels, otherwise sloughing of their margins may mar the result.

The flaps turned aside, dissection proper begins, and this must be methodical and systematic, the operator proceeding cleanly from step to step. Knife and scissors only are used, blunt dissection either with an instrument or the finger, though hard to resist, is prohibited, and will certainly lead to disaster from rupture of a cascating gland, or from tearing of veins. The first step is to define clearly the borders of the sternomastoid by incising the deep cervical fascia along its margins. The deep surface of this muscle is cleared from the lowest lying glands and retracted backwards, and the inferior belly of the omohyoid cleaned and retracted downwards. This exposes the carotid sheath, which is deliberately opened from behind by a small vertical cut, below the largest palpable gland: if opened from behind, the cellular tissue of the sheath with the loop of the hypoglossal nerve is easily pushed forwards out of harms way. If the lower deep cervical glands are enlarged and are to be removed at a second stage operation, an artificial separation must be made, a more difficult procedure: otherwise it is essential that the lowest glands are taken

first. The glands are now stripped from behind and below, upwards and forwards, until the common facial vein is reached: by working forwards the large middle thyroid veins are seen and secured before division, as is the common facial vein not too close to its junction with the internal jugular.

At this point I always abandon the dissection from the front and start removal of the glands from the muscles forming the floor of the posterior triangle, working from below, upwards and forwards. Here caution is needed until the spinal accessory nerve is found, sometimes above, sometimes below, sometimes imbedded in the glands: once found it is picked up on a blunt hook, and deliberately isolated until it is lost to view as far forwards as possible beneath the sternomastoid: the glands can then be freed from the posterior triangle muscles, and from the deep surface of the sternomastoid until the whole mass is pushed beneath that muscle to the front. The anterior primary divisions of the cervical nerves lie beneath a distinct layer of fascia on the floor of the posterior triangle, and, provided rough dissection does not open this layer, they are not in any danger. The dissection is resumed in front of the sternomastoid, working upwards and forwards, the spinal accessory nerve picked up again and freed to the point where it disappears from the operation field across the transverse process of the atlas beneath the digastric muscle: the posterior belly of this muscle, lying at about the same level as the common facial vein already isolated and ligatured, forms the next landmark, and, keeping in this plane, the glands are freed forwards and upwards until their limits are reached. Part of the parotid gland may be shaved off with a knife, and the submaxillary salivary gland is removed together with the submaxillary and submental glands: all these lie on the fascial plane which covers the digastric, hyoglossus and mylohyoid muscles, which fascia effectually protects the vessels and nerves of this region. The deep part of the submaxillary gland lying on the hyoglossus can be taken if need be, and in every case Wharton's duct is crushed, cauterized and ligatured, but if this is done a deep wound is left at the side of the tongue at the bottom of which deep bleeding, difficult to control, is apt to occur. The dissection is completed when the uppermost and most anterior (submental) glands are freed and the whole mass, which is usually of cruciate shape with limbs 3 or 4 inches in length, is removed. Scrupulous arrest of bleeding, irrigation of the wound with hot saline, suture as described, with provision for drainage through a stab in the lower flap, a very thick pad of gauze and wool, and a bandage secured to the jaw with collodion complete the operation. The large dressing, which takes in the head and both axillæ as well as the neck, acts as a

OXYGENATION OF THE PERITONEAL CAVITY IN THE TREATMENT OF TUBERCULOSIS OF THE ABDOMEN*

By NANDLAL BORDIA, M.B., B.S.

*District Medical Officer, Indore District, Indore, and
Medical Officer in charge, Rao Sanatorium*

IN this article I propose to deal with the treatment of abdominal tuberculosis by oxygenation of the peritoneal cavity without making any reference to general treatment, so as to make the article reasonably brief and concise.

* Rearranged by the Editor.

(Continued from previous column)

splint to secure immobilization of the operation area. The dissection may take perhaps 75 minutes and it is not surprising that it is associated with some shock, which passes off quickly once the wound is dressed and the usual restorative measures adopted. This description applies to the commonest type of case where the upper, anterior and posterior groups of the vertical chain are the most extensively infected. In other groups the same principles apply: adequate flaps with a transverse incision, clear definition of the important anatomical structures and complete removal of the glands by sharp dissection from these structures, commencing at the periphery, where the least infected and least adherent glands are most easily freed.

The dangers of the operation are nerve injury and hæmorrhage: both are avoided by clean cutting and adequate incisions. The spinal accessory must always be isolated and recognition of fascial planes will protect the others. Veins should be secured before division: deliberate exposure at an early stage protects the internal jugular vein: a wound of this size may be safely closed with a lateral ligature and there need be no hesitation in excising a segment with adherent glands, a procedure which is simple if its lower end has been cleanly isolated. The danger of air embolus has probably been exaggerated and can only result from rough operation.

Convalescence is usually smooth: some swelling around the wound from exudation of lymph from divided lymphatics is inevitable and is minimized by the abundant pressured dressing. A diffuse tuberculous cellulitis which causes swelling of the whole of the side of the neck is an unfortunate but rare complication.

The view is advanced that under the conditions prevailing in this country, early radical operation is the soundest method of dealing with the local manifestations of cervical glandular tuberculosis, and some points in the practical surgical technique are stressed in the hope of encouraging this view.

In Central India tuberculosis of the abdomen is often found without being associated with pulmonary tuberculosis. It is the commonest form of tuberculosis met with in this part of the country and lung infection is usually secondary to abdominal disease. For some years the treatment adopted has been exploration of the abdomen and again closing the peritoneal cavity without doing anything inside. This was found to be useful. It was believed that it is the exposure to the atmospheric air, or probably oxygen contained in the air, that inhibited the growth of the tubercle bacilli. On this assumption Lieut.-Col. Tyrrell introduced intra-peritoneal administration of oxygen, about the year 1920. In all cases of abdominal tuberculosis a preliminary exploration of the abdomen was first performed to confirm the diagnosis and to ascertain if there were any adhesion of the gut to the peritoneum forming the part of the anterior abdominal wall. The abdomen was opened by a one-and-a-half-inch-long incision in the middle line, the contents were examined visually and by introducing a finger to feel any glands, adhesion, matting of the gut, or thickening of the peritoneum. If there was any evidence of tuberculosis the abdomen was closed and a small cannula of 1 mm. bore was introduced inside near the last knot in the peritoneum. The wall was sutured, the outer end of the cannula being kept out and the inner end inside the cavity. Now oxygen was introduced in the following way:—

Two flasks (wash bottles) of 500 c.cm. capacity, one of which is graduated, with the necessary rubber connections are required. The graduated flask is filled with perchloride lotion (1 in 1,000). Oxygen is passed from the cylinder into the graduated flask displacing the lotion into the second flask. The graduated flask is now connected with the cannula and by raising the second flask the oxygen is forced into the peritoneal cavity. The level of the lotion in the graduated flask indicates the amount of oxygen introduced.

Nowadays preliminary exploration is tried only in doubtful cases. If there is a tumour or suspected adhesion, exploration is done first, otherwise in every straightforward case oxygen is introduced by the following way:—

The skin and the abdominal wall are anaesthetized by 1 c.cm. of 2 per cent novocaine solution. The site chosen is about 1 inch below and lateral to the umbilicus. A sharp-pointed Graefe's knife is plunged perpendicularly through the skin, subcutaneous tissue and muscle at the anaesthetized spot. The trocar with the cannula attached is introduced into the knife puncture and gentle pressure applied. As soon as the peritoneum is punctured the patient experiences a sharp pain. Now the trocar can be pulled out leaving the cannula *in situ*, which then is freely movable up and down if it is inside the

cavity. There is no danger in this procedure as the end of the cannula is blunt. Now the adaptor is fitted to the outer end of the cannula and gas allowed to flow in. The lotion in the flask rises freely if the gas is escaping into the peritoneal cavity.

Difficulties during operation

(1) It may be difficult to judge when the peritoneum is reached, but free movement of the cannula by manipulation and free escape of gas are enough to show that the cannula is inside, otherwise the trocar must be introduced into the cannula and further bored down to penetrate the peritoneum. In a short time after doing a few oxygenations the operator can easily judge when it is inside.

(2) Even if the peritoneal cavity is reached the omentum may block the end of the cannula, but it can be easily cleared by moving the cannula up and down and allowing gas to flow under pressure by raising the flask.

(3) The gut may be punctured if it is adherent to the abdominal wall and a faecal fistula may result. But in such doubtful cases exploration of the peritoneal cavity must always be tried first.

(4) Any of the large blood vessels may be punctured if the trocar is introduced injudiciously. I have never met with the last two accidents yet, and have seen and done the little operation hundreds of times.

How much gas to introduce.—After exploration about 200 c.cm. of gas is sufficient on the first occasion, but the quantity on later occasions varies according to the size of the abdominal cavity. Formerly, when oxygen was introduced without measuring, the hollow note produced by percussing was a sufficient indication that the abdomen was full of gas. The obliteration of liver dullness is another good indication that enough gas has been introduced, provided there are no adhesions.

Every week the quantity is increased till about 350 to 400 c.cm. and, rarely, even 500 c.cm. of oxygen are introduced at each operation. If there are adhesions it may be impossible to introduce more than 100 c.cm. without causing severe pain afterwards. Therefore, it is always wise to start with a small dose and then increase it gradually watching the condition of the patient.

Post-operative complications

(1) *Pain.*—This is a common complaint when the quantity of gas introduced is a large one, i.e., after 500 c.cm. at the first sitting or if there are adhesions inside.

(2) *Temperature.*—In the majority of cases the temperature tends to fall in uncomplicated cases, but if associated with extensive pulmonary tuberculosis the temperature may shoot up if a large amount of gas is introduced.

(3) *Dysentery-like condition*.—Rarely, on account of congestion of the vessels, there is a blood-stained exudation inside the intestine and mild attack of a dysentery-like condition may result, which subsides as soon as the gas gets absorbed, usually in 4 or 5 days.

(4) *Surgical emphysema*.—If the gas is allowed to escape into the abdominal wall this complication occurs, but is not troublesome.

Results

I. In the early stages when there are minute tubercles on the peritoneum this form of treatment is at its best.

There are records of a very large number of cases, but it will be sufficient to quote only a few here:—

Case I.—A Mohammedan Bohra female, aged 25 years, was admitted to the M. T. Hospital for abdominal pain and high continued fever, the temperature ranging from 103° F. to 104° F. She was very weak and weighed 68 pounds. She was delivered of a child two months ago, following which she started getting high temperature and was treated as a case of puerperal sepsis, but to no effect. There was history of diarrhoea, abdominal pain and fever for five months before her pregnancy.

Twenty days after her admission on the 8th March, 1936, she was given 150 c.cm. of oxygen without exploration of the abdomen. The temperature came down to 100.6° F. next morning but rose to 103° F. in the evening, and varied from 100° F. to 102° F. afterwards. She was again oxygenated on the 15th March.

After four days her morning temperature became normal but the evening rise persisted. After the fourth oxygenation she was completely afebrile. Her pain subsided gradually. She put on eight pounds in weight when she left the hospital. The patient is still under observation with no complaints whatsoever.

Case II.—A Baniya female, aged 16 years, was admitted to the M. T. Hospital, Indore, on the 16th July, 1933, complaining of pain in the abdomen, occasional diarrhoea, loss of appetite and nausea for the last nine months. Her temperature was 101.4° F. in the evening. Liver and spleen were not enlarged. Abdominal wall was slightly rigid. She was operated on on the 19th July. The abdomen was opened by a one-and-a-half-inch-long incision. The peritoneum was thickened and studded with minute tubercles. There were no adhesions. Glands were enlarged in both iliac fossae. The abdomen was closed and 200 c.cm. of oxygen were put in. Every week 300 c.cm. of oxygen were given and after four oxygenations her temperature was completely normal. Her pain subsided partly after the second oxygenation and completely after the fourth. Her weight increased by six pounds in one and a half months and she was discharged on the 28th August.

At present she is quite well and has no complaints.

Case III.—Female, aged 18 years, married, was admitted on 16th October, 1931, complaining of abdominal pain and occasional distension for two years. She was very constipated and had no appetite. She had medical treatment in several dispensaries in the Central Provinces. Her temperature was 100° F. in the evening. Pulse was 102 per. minute on admission. The liver was palpable but not the spleen. She had amenorrhoea for the last ten months. She was explored on the 25th October, when minute tubercles were seen all over the gut, and 200 c.cm. of oxygen was put in. She was re-oxygenated every week. After the sixth one her pain disappeared and her maximum temperature was 99° F. Bowels were still constipated. She was discharged on 28th December without any complaint.

II. Many cases have been admitted for intestinal obstruction, and on opening the abdomen

most of these cases showed extensive adhesions and matting of loops of intestines. These cases were not acute to start with, but really sub-acute or chronic; later, acute symptoms followed. No surgical treatment could be done in some cases but only oxygen was introduced. The postoperative treatment consisted of fractional doses of calomel and pituitrin by injection. The obstructive symptoms passed off gradually in 48 hours. It is surprising that these cases improve remarkably well under oxygen treatment.

S., aged 26 years, was admitted for intestinal obstruction on 3rd July, 1936. The abdominal examination revealed visible peristalsis. Her temperature was 100° F. to 104° F., and pulse 110 per minute on admission. On opening her abdomen a mass of matted intestines was found on the left side below the level of the umbilicus. The peritoneum was studded with tubercles and there were dense adhesions with the coils of intestines. The abdomen was closed and 100 c.cm. of oxygen were put in. The obstructive symptoms passed off in 48 hours by the usual medical treatment. Every fifth day she was given about 200 c.cm. of oxygen. She has now improved in health and her weight has considerably increased. She gets no fever and has no constipation.

R., a Mohammedan female, aged 20 years, was admitted on 30th March, 1934, for acute intestinal obstruction. Her abdomen was opened. A tuberculous stricture near the lower end of the ileum was found. A side to side anastomosis was done. The whole peritoneum was studded with tubercles. The abdomen was closed after introducing 100 c.cm. of oxygen. Later, this was increased by 50 c.cm. each time till 400 c.cm. on the seventh sitting. After a number of oxygenations, she was treated as an out-patient. She used to be detained in the hospital for four hours after oxygenation, and then she was permitted to go home every time. She was used to get pain if oxygenation was not repeated within a fortnight. The patient is now doing very well and has put on weight. Her temperature is normal and her bowels regular.

III. In ascitic cases the effect is not well marked. The oxygen appears to take a longer time to be absorbed. No exploration is necessary except when the fluid is loculated. Repeated tappings with oxygenation through the same cannula opening have cleared up some cases.

IV. In cases with enlargement of glands in the abdomen oxygen takes a long time to reduce the size of the glands, but it does effect this in time.

Probable mode of action

Oxygen induces hyperæmia of the whole peritoneum, as can be observed. This increased blood supply naturally helps to combat the disease.

The oxygen saturation of the tissues inhibits the growth of tubercle bacilli.

Conclusion

There appears to be no doubt that oxygenation is an effective remedy in the treatment of abdominal tuberculosis. During the past few years I have observed in all about two hundred cases treated by this method, some of which were diagnosed by laparotomy. They have certainly improved. Most of these cases were not given any other treatment. Many of them

were very poor people who could not afford to purchase costly drugs. The effect of oxygen after laparotomy or without it appears to be equal. I think there is no reason why the abdomen should be opened up in every case when nothing radical is to be done. It should therefore be reserved for those doubtful cases where it is not safe to introduce oxygen without knowing the exact condition. I have quoted some of the cases which have improved remarkably. There are many which have been benefited partially. Lieut.-Col. Tyrrell, who has been trying the treatment for the last 16 years, does not claim that it cures the disease, but it is evident that, in a large majority of cases, oxygenation relieves the symptoms and improves the general condition and weight. The temperature subsides and pain gradually passes away. Usually six to eight oxygenations are necessary to effect relief of symptoms.

There are many cases who have not been benefited by this treatment and most of these were advanced cases or those in which the lungs were badly affected. There are many cases who left off treatment early and thus they could not be observed. A rough record of the past four years of tuberculosis of the abdomen treated by oxygenation of the peritoneal cavity in the M. T. Hospital is as follows:—

Number of cases—197.

Total number of oxygenations	..	685
Cured	..	34
Relieved	..	58
Doubtful results (did not attend)	..	64
Died or discharged otherwise	..	41

(Most of the patients were females and between 14 and 25 years of age.)

Alternative methods of oxygenation

Instead of the flasks, a Lillingston and Pearson's artificial pneumothorax apparatus can be conveniently used for the purpose.

Further, a football bladder can first be filled with oxygen from the cylinder and a pinchcock put up on the tube of the bladder. It can be removed to any place and oxygen can be introduced by connecting the bladder to the cannula through a tube. It is convenient to carry the whole apparatus but correct measuring is not possible.

(The bladder should be sterile from inside and the oxygen should be used within a day or two after filling the bladder otherwise it develops a smell from the rubber, though chemical analysis of the contained oxygen does not show any harmful impurity, such as sulphurated hydrogen, carbon dioxide or sulphur dioxide.)

I am much grateful to Lieut.-Col. J. R. J. Tyrrell, I.M.S., C.I.E., Inspector-General of Hospitals, Holkar State, Indore, who has kindly permitted me to issue this article and under whose supervision I had the opportunity of studying this subject.

Note

By J. R. J. TYRRELL, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

In the above note an attempt has been made by one of my assistants, Dr. Nandlal Bordia, to draw attention to prevalence and importance of abdominal tuberculosis in this part of India and to describe measures which are being taken for the treatment of the condition.

Some ten years ago when serving in Kathiawar, my attention was drawn to the fact that the abdomen, particularly the caecal region, is one of the commonest sites of a primary tuberculous infection and that thoracic and lung infections are usually secondary to abdominal.

In the early stages such patients give very vague and indefinite symptoms and even the closest examination may fail to disclose any palpable mass or painful area in the abdomen, so previous to this time I and my colleagues in Kathiawar were accustomed to diagnose such cases as appendicitis, dyspepsia, debility, constipation, dental trouble, and in females pelvic or uterine trouble.

It was when doing abdominal operations for other conditions that I was struck by the frequency one found evidence of tuberculosis not previously suspected which led my colleagues and myself to look for these cases and to try to detect them. We found them to be quite common and that same yielded to general treatment combined with rest in bed and exposure to sun, etc. Many however would not respond so favourably and so it was decided to try the effects of oxygen intraperitoneally. The procedure followed was to make a small incision, which would admit one or two fingers, examine the abdomen, and make certain of the diagnosis. After stitching up the wound 100 to 500 c.cm. of oxygen were passed into the peritoneal cavity. After some days when the charge was absorbed and according to the general condition of the patient a further charge was introduced, but on this and subsequent occasions this was done by passing a fine trocar and cannula through the abdominal wall and introducing the oxygen through this.

The number of times this little operation had to be done depended on progress.

I was so impressed by the improvement, in even the most advanced cases of abdominal tuberculosis, some with even complete obstruction, that I continued using the same treatment on my transfer to Indore some seven or eight years ago.

When I came here, I found conditions as in Kathiawar, namely, that very few cases of abdominal tuberculosis were being recognized, but in a few months we found it to be, as in Kathiawar, by far the commonest seat of primary infection.

I am not aware whether this holds true for other parts of India, but from my experience, in two such distant and dissimilar places as Kathiawar and Indore, it leads me to suspect that it may be so. I would therefore suggest that those interested in the rapidly spreading disease of tuberculosis should particularly look for an early abdominal infection, which may be present long before the x-ray will disclose any abnormality in the chest or even before any sign can be found in the abdomen unless they are looked for very carefully.

[Note.—In view of the observations of the authors, the possibility of the intestinal route as the portal of entry of the tubercle bacillus in Western India should be further investigated. Work done in Calcutta, under the auspices of the Indian Research Fund Association, has shown that it is comparatively rare (only 5.1 per cent) and that the human tubercle bacillus is the causative organism. The authors of the present paper do not, however, adduce any evidence from autopsy material in support of their opinion.—EDITOR, I. M. G.]

INTRA-PLEURAL PRESSURE

INTERPRETATION OF MANOMETRIC READINGS IN THERAPEUTIC ARTIFICIAL PNEUMOTHORAX

By T. J. JOSEPH, B.A., M.B., B.S.

Medical Superintendent, Pendra Road Sanatorium, Central Provinces; formerly of the U. M. T. Sanatorium, Arogyavaram (Madanapalle)

IN India, artificial pneumothorax (A P) is becoming rapidly established as an indispensable adjunct to the treatment of pulmonary tuberculosis. In the induction of A P the manometric readings of intra-pleural pressure (I P P) form one of the chief guides to the operator both in induction and in dosage; so much so, that the manometer has been described as the 'heart of the apparatus' and as the 'eye of the operator'.

In this article it is proposed to give a few observations on the physiology of I P P, and its variations in health and disease, with special reference to A P. The observations are based on no less than 21,000 separate readings of I P P made in the U. M. T. Sanatorium, Arogyavaram, of which over 6,000 have been made by the author personally.

The physiology of I P P

It is a well-known fact that the pressure in the adult pleural cavity is negative, i.e., less than the atmospheric pressure. The pressure is more negative during inspiration, less so during expiration, but always negative. The negative pressure is equal to the elastic tension of the stretched lung. It is greater the more the lung is expanded and *vice versa*.

In the healthy expanded lung pulmonary equilibrium in the thorax is obtained by the interplay of mainly three forces:

(1) The elastic recoil of the lung inherent in the elastic fibres which so largely make up lung tissue, tending to make the lung retract or collapse towards its roots.

(2) The atmospheric pressure acting on the inner surface of the lung through the air-passages (the outer surface being protected from the atmospheric pressure by the chest wall) and tending to keep the lung expanded.

(3) The force of cohesion between the opposing surfaces of the visceral and parietal pleurae tending to prevent their separation.

It has been demonstrated experimentally that when an unopened thorax is enclosed in an airtight bell-jar and the air exhausted by means of an air-pump (thus eliminating the atmospheric pressure acting on the inside of the lungs), the lungs still remain expanded and the two layers of the pleura unseparated. This shows that the force of cohesion alone (unaided by the atmospheric pressure) is able to overcome the tendency for elastic recoil of the lungs. However, as soon as the two layers of the pleura are separated from each other by ever so small a distance, as by introducing a small quantity of air into a free

pleural cavity, the force of cohesion is immediately and completely nullified. Then if by any means atmospheric pressure is put in communication with the pleural cavities, or, in other words, the pressures inside and outside the lungs are equalized, then the elasticity of the lungs will act unopposed and the lungs will collapse. This is illustrated by the phenomenon so often seen on the post-mortem table where the lungs collapse considerably as soon as the chest wall is opened. This will also explain the fact that, with a healthy lung or with a diseased lung which is not consolidated by exudate or hard fibrous tissue or other solid tissue, no positive pressure in the pleural cavity is required to bring about a collapse of the lung.

Measurement of intra-pleural pressure (I P P)

The introduction and use of the water manometer in connection with the therapeutic administration of pneumothorax is attributed to Saugmann of Vejlebjerg Sanatorium, Denmark, in 1906. Since then and before, phthisiologists in different countries have used various kinds of manometers and modes of recording pressures, so that there has been a great deal of confusion in comparing results. Some have used the U-type of manometer employing mercury, bromoform and oil, glycerine and chloroform, water, etc., as the liquids, while others have used different types of aneroid manometers. Some have recorded the displacement of water in the open limb of the U-tube manometer as measuring the pressure, while others have doubled this reading in order to get the 'true' pressure. There has also been great diversity in the bore of the needles and manometer tubings used.

Manometers of great complexity have been devised for measuring intra-pleural pressure. One such is the 'ergomanometer' devised by Prof. Parodi of Italy. It is claimed that this instrument is capable of measuring, by means of four separate manœuvres, the following four factors:—

- (1) The amplitude of thoraco-diaphragmatic movement,
- (2) the power of expansion of the lung,
- (3) the strength and fixity of the mediastinum, and
- (4) the power of expiratory compression.

Factors causing variations in I P P

The factors which bring about variations in I P P and its measurements are: (a) those pertaining to the apparatus used and (b) those intrinsic to the patient.

(a) Pertaining to the apparatus

Of course it is understood that the factors which pertain to the instrument do not alter the actual I P P, but influence only the measuring and recording of it. Such factors are the fluid in the manometer, the calibration of the manometric scale, the bore of the needle and the diameter of the manometer tube.

It is now almost universally accepted that the U-tube type of manometer is to be preferred, that water is the best fluid to be used in the manometer and that the pressure is to be recorded in centimetres of water column, the total difference between the levels in the two limbs of the manometer being taken as the 'true' pressure.

It will be readily understood that the pressure in the manometer is shown as a result of an equalization of pressures between the air in the closed limb of the manometer and the connecting tube on the one hand, and the air (or absence of air) in the pleural space on the other hand. This equalization depends upon the rate of flow of air through the needle. The rate of flow of air through a capillary tube, such as a needle, depends upon its length and its bore. Physicists have established that if the length is halved the rate of flow is doubled, and if the diameter of the bore is halved the rate of flow is reduced 16 times. It will also be seen that the smaller the amount of air in the connecting tube the quicker the equilibrium above mentioned will be established and therefore the quicker and sharper the manometric response will be. The smaller the bore of the needle and the larger the volume of air in the connecting tube the less sensitive the manometer will be, and the greater will be the departure of the manometric readings from the correct value. It has also been shown, by connecting the same pleural space to manometers of different calibre, that the wider the tube the less sensitive the manometer becomes.

Therefore, from a purely mechanical point of view, the ideal arrangement would be to have a wide bore needle connected to a narrow bore manometer with as short a rubber tube as possible. However the manometer tube should not be less than about 3 mm. in diameter as otherwise surface tension and capillary force would interfere with the working of the manometer.

Recently the American Sanatorium Association appointed a committee for the standardization of the A P apparatus. This committee has now made the following recommendations :—

(1) For the manometer and connecting tube a diameter of 3 to 5 mm.; the connecting tube to be as short as is practically possible.

(2) For the pneumothorax needle 0.8 to 1.2 mm. diameter, the needle to be 2 to 2.5 inches long.

(b) *Factors intrinsic to the patient*

1. *Age*.—In the new-born infant there is hardly any negative I P P. In the eight-day-old infant the negative I P P was found by Hermann to be only 0.4 mm. of mercury (or 5.4 mm. of water). The high negative I P P observed in the adult thorax is developed gradually. It is due to the fact that the size of the thorax increases more rapidly and to a greater extent than the lungs. To fill this

enlarging cavity the elastic lungs become more and more expanded and thus the negative I P P is established. In the healthy chest the maximum negative I P P is attained when the chest has grown to its maximum size. Often in old age the negative I P P declines again on account of loss of elasticity of the lungs due to emphysema and other causes.

2. *Depth of breathing*.—During inspiration the chest cavity expands increasing the tension of the already tense elastic fibres in the lung. This shows itself in the pleural cavity as an increased negative pressure. The deeper the breathing the greater the fluctuations of the manometer. During the induction of A P it often happens that a sudden deep expiration, as when the patient coughs, the fluid in the manometer is forced out of its open end. Hence the necessity to get the patient to breathe normally and regularly before recording the readings of the manometer.

3. *Position of the patient*.—It has been found experimentally and in actual therapeutic practice that the I P P is higher (less negative) in a dorsal position than in a lateral position. Some observers have noticed a difference of as much as 10 cm. of water pressure caused by change of posture. Whether the weight of the lung plays any part in the causation of this difference is still a subject of controversy among phthisiologists.

4. *Site of puncture*.—Sisti and Cati in the Benito Mussolini Institute (now Carlo Forlanini Institute), Rome, demonstrated the difference in pressures between the upper and lower parts of the pleural cavity by introducing two needles into the same pleural cavity of a dog, one near the apex and the other near the base, and recording on a revolving drum the two intrapleural pressures simultaneously while the dog was made to breathe quick and deep. The curves obtained by them are reproduced below.

It will be noticed in the graph that the amplitude of oscillation is greater at the base than at the apex and that at the base the values approach the zero point during expiration.

5. *Condition of the lung and pleura*.—In any condition in which the tendency for collapse inherent in the lung is increased, the pleural cavity will show an abnormally high negative pressure (for normal I P P see below). Commonest among such conditions are :

(a) *Tendency to atelectasis*.—When in any part of the lung the bronchi are blocked by disease or other causes, the air in the corresponding alveoli of the lung is absorbed and the tendency for collapse in that area becomes so great that it often causes retraction of the adjacent chest wall and displacement of the mediastinum towards the same side. The pleural cavity of such a lung, even though the atelectasis is only partial, will show a very high negative pressure, — 20, — 30, or even more, cm.

of water, and as soon as a small quantity of air is introduced and the force of cohesion between the two layers of the pleura is overcome the lung collapses quickly.

(b) *Extensive fresh fibrosis of the lung.*—Here the lung collapses more quickly even than healthy lung tissue. On the other hand, if the fibrosis is old-standing and hard, collapse is more difficult than in a normal lung.

that a yielding mediastinum moves in and out with the movement of the chest wall on the side of the A P, thus preventing great increase in the volume of the chest cavity during inspiration. (In the phenomenon called 'mediastinal flutter' which takes place in an open pneumothorax due to a large opening in the chest wall or during thoracoplasty operations, the movements of the mediastinum are the reverse of the

The above two factors, namely, the tendency to atelectasis and fresh fibrosis, are probably the chief causes of the phenomenon known to phthisiologists as 'selective collapse', or the collapse of the diseased part of a lung while its healthy part remains expanded.

When the two layers of the pleura are extensively adherent, and only small pockets of free pleural spaces are left, these free spaces are often found, contrary to expectations, to show high negative pressures. In fact some of the highest negative pressures met with in the practice of A P are in small pleural pockets where the pleural walls have become thick and unyielding due to old pleurisy. Here the high negative pressure is not due to the power of elastic recoil of the lung, but to the fact that, when air in such a pocket gets absorbed, the lung is prevented by the thick pleura from expanding and filling up the space. This pleural space is converted into a comparative vacuum with a high negative pressure. A small quantity of air introduced into this space will quickly convert this high negative pressure into a high positive one. The following two examples will illustrate this point:—

J., girl, aged 18 years.

7-2-36. —7—1, 100 c.c. —1+2.

A P abandoned after a second trial on 8-2-36.

R., man, aged 35.

5-10-35. —14—1, 300 c.c. —6+3.

7-10-35. —10+2, 300 c.c. —6+6.

13-10-35. —14+10, 300 c.c. —6+20.

(Patient breathing hard.)

Fluoroscopy revealed only a small pocket of air at the base. A P abandoned on account of ineffective collapse.

6. *Condition of the mediastinum and diaphragm.*—Where the mediastinum is very flexible and easily displaced the manometric oscillations are 'damped', i.e., smaller and more sluggish than otherwise. This is due to the fact

above and tend to asphyxiate the patient by compressing the healthy lung during inspiration.) Communication between the two pleural cavities through the mediastinum, said to be common among some lower animals, is almost unknown in human beings.

In bilateral A P even, when the pressure on one side is negative, the mediastinum may be found by fluoroscopy to be displaced far to the other side. This makes smaller refills at more frequent intervals and more frequent fluoroscopic examinations very necessary.

It is mainly the action of the diaphragm which causes the inspiratory increase of the negative pressure in the pleura. Therefore when the diaphragm is paralysed as a result of phrenic interruption this inspiratory increase in the I P P is reduced. If the diaphragm moves paradoxically this reduction will be all the more marked.

Example:—

B. R., girl, aged 19 years. A P right side.

(37) 26-3-36. —16—6, 300 ± 0 + 6.

(38) 27-4-36. —20—4, 400 + 6 + 12.

9-5-36. Phrenic evulsion was performed on the right side.

18-5-36. Fluoroscopic examination showed diaphragm paralysed, no effusion in A P.

(39) 28-5-36. —6—3, 100 c.c. + 2 + 4.

(40) 27-6-36. —6+1, 100 c.c. + 5 + 8.

7. *Contents of the pleura.*—Effusion into the pleural space, or escape of air into the pleura from the lungs (pleuro-pulmonary fistula), will increase the I P P and change it quickly to positive with small quantities of air. In fact, during therapeutic pneumothorax often the first sign of on-coming pleural effusion is the increase in I P P. This increase is not only due to the fluid taking up space and compressing the air but also partially due to reduced absorbing power and increased rigidity of the pleura on account of the pleurisy preceding effusion.

Often a large increase in pressure is noticed when the quantity of fluid formed is small.

L., girl, aged 17.

- (18) 4-5-35. — 7—2, 500 + 1 + 4.
 20-5-35. Fluoroscopy; effusion, small quantity.
 (19) 22-5-35. — 8—1, 150 + 5 + 8.
 (20) 15-6-35. — 7—1, 100 + 8 + 10.
 5-11-35. Physical examination, no effusion.
 (27) 2-12-35. — 12—8, 300 + 1 + 6.
 23-12-35. Fluoroscopy, — no effusion.

When a spontaneous pneumothorax is suspected, it is the practice to introduce the A P needle and note the pressure in the pleural cavity. If the hole in the visceral pleura is a valvular one admitting air into the pleural cavity during inspiration but preventing its escape during expiration, the I P P will be found to be very high, may be +20 or +30. If the hole is a large one, remaining open both during inspiration and expiration, the I P P may not be high but it will be found not to change to negative even after taking out large quantities of air. In such cases a continuous aspiration of air from the pleural cavity is indicated.

K., man, aged 32.

- 1-6-36. Spontaneous pneumothorax suspected. I P P — 2 + 4; after taking out 500 c.c. of air — 2 + 4. After taking out another 500 c.c. pressure same.
 5-6-36. Patient very breathless. Pressure — 2 + 6; after taking out 1,000 c.c. of air — 2 + 5; continuous aspiration of air established.

Normal intra-pleural pressure

The factors which alter the readings of the manometer being so many and varied it is not easy to give figures which form the limits of normal I P P. According to Von Muralt (quoted by Sewall), after the initial introduction of gas into the pleural cavity free from adhesions, the manometer registers a mean average pressure of — 6 to — 8; during inspiration — 10 to — 12; during expiration — 4 to — 2; during deep inspiration up to — 20. Bunta gives the range of average I P P before inflation in uncomplicated pleura as — 7 to — 5 and MacLeod — 13.6 on inspiration and — 6.8 on expiration. Aron, quoted by Bunta, made 36 observations on a sound man and got the average tension at the end of quiet inspiration — 6.3 and at the end of quiet expiration — 4.1. At the U. M. T. Sanatorium, Arogyavaram, the average of 80 readings before the first two introductions of air in 40 cases where subsequent fluoroscopic examination showed good collapse was — 10.4 on inspiration and — 6 on expiration. All the pressures given above are in centimetres of water.

Interpretation of manometric readings in artificial pneumothorax

When a needle is introduced through the chest wall for an induction of A P the manometer might behave in various ways:—

1. *Normal movements.*—If the needle end is correctly placed between the two layers of a

free pleura and if the needle is not blocked, a pressure round about the normal given above will be registered. If the negative pressure is high enough, say up to 4 or 5 cm. of water, and the oscillations are regular and especially if the pressure remains negative both during inspiration and expiration, then it is safe to introduce air.

2. *No movements.*—The needle end may be in the chest wall, in an adherent pleura, or in a pleural effusion; or the needle may be blocked by tissues, blood or moisture in the needle.

3. *Small movements about zero.*—Sometimes the manometer oscillates round about zero showing a small negative on inspiration and a small positive on expiration. When this happens the needle end may be in the pleural cavity or in the lung. It is not advisable to introduce any air unless there is reason to believe that the needle end is in the pleural cavity. The same type of movement with a wider amplitude, say — 5 + 4, may be obtained with the needle end in a fair-sized bronchus or in a superficial cavity with an open bronchial inlet.

Suppose the reading obtained is — 3 + 3. To know whether the needle end is in the pleural cavity or not, the patient may be asked to take a deep breath and hold it. If the higher negative pressure, say — 6, produced during this inspiration remains steady while the breath is being held, the needle is probably in the pleural cavity. If the higher negative pressure produced slowly falls, the needle is in the lung, a bronchus or a pulmonary cavity. Small or sluggish movements may be caused by partial blocking of the needle.

4. *Irregular movements.*—The manometer might show a good negative without further oscillations. The needle end has probably passed through a free pleural space and touched the lung. The indication is to withdraw the needle a little and gently clear it with the stilette.

If the manometer rises on the positive side in jerks synchronous with the pulse, the needle end is in an artery. If it does so slowly without jerks the needle end is probably in a vein. (The needle when withdrawn will be found to drip blood.) In either case no air should be introduced for fear of the dread accident of air embolism. (Some have asserted that the needle end in a pulmonary vein would show a negative pressure. There is no evidence for this.)

5. *Reversed movements.*—If the movements of the manometer are reversed, i.e., more negative during expiration and less negative or slightly positive during inspiration, the needle end is probably below the diaphragm in the peritoneal cavity. 'Dragging' or slightly reversed movements can happen with the needle in the pleural cavity when the diaphragm is adherent to the chest wall, or when it is moving paradoxically due to paralysis.

6. 'Falling manometer'.—The manometer is said to fall when an initial high positive pressure slowly becomes less and less with every oscillation or actually becomes negative. This happens after admission of air into the pleural space and is due to the slow separation of slightly sticking pleural surfaces or due to the diffusion of air between adhesions or into the recesses of the pleural cavity.

Summary and conclusions

1. The causation and physiology of intra-pleural pressure (I P P) are discussed.
2. Factors causing variations in manometric readings during the measurement of I P P are described.
3. The recommendations of the American Sanatorium Association for the standardization of the artificial pneumothorax (A P) apparatus are discussed and summarized. The adoption of these recommendations as the standard in India would facilitate the comparison of results by different observers.
4. The interpretation of different types of manometric readings in A P and allied conditions, such as bilateral A P, A P with phrenic evulsion, spontaneous pneumothorax, etc., are discussed and illustrated.
5. The importance of a correct interpretation of manometric readings in the practice of A P is emphasized. The induction of A P without the aid of a manometer should be looked upon as 'criminal negligence' on the part of the operator.

TREATMENT OF TUBERCULOUS HÆMOPTYSIS BY SUBCUTANEOUS EMPHYSEMA

By U. P. BASU, M.B., F.R.C.P.I., F.S.M.F.
Professor of Clinical Medicine (Offg.), Medical College, Calcutta

BETWEEN January 1935 and October 1936 altogether 97 cases of pulmonary tuberculosis were treated by me in the tuberculosis wards of the Calcutta Medical College Hospitals. Of these 61 were males and 36 females. Hæmoptysis was present in 46 cases—among whom 36 were males and 10 females. Initial hæmorrhage was present in 26 cases, recurrent in 9 cases, late in 8 cases and fatal in 3 cases. It is thus evident that in my series of cases a large number of patients manifested this symptom. Gonzalez de Véga and Perez (1935) reported successful treatment of tuberculous hæmoptysis by subcutaneous injection of air varying from 200 to 300 c.cm. at the posterior axillary line at the level of the 8th, 10th or 11th ribs by a pneumothorax apparatus, in a series of 4 cases. Following this line of treatment subcutaneous emphysema was produced by means of the pneumothorax apparatus in the following 5 cases with admirable result in 4 cases, the amount of air injected at a time being 250 c.cm. in each case.

CASE REPORTS

Case I.—S. C., Chinese male, aged 25, admitted on 4th May, 1936, with profuse hæmoptysis of five days' duration. X-ray examination revealed extensive infiltration of the left lung and early infiltration of the right sub-apical region. The sputum was positive. The patient received morphia, calcium, emetine, two intravenous injections of congo red (1 per cent), 10 c.cm. each, up to 11th May without any improvement. On 11th May all treatment was stopped and 250 c.cm. of air were injected subcutaneously into the lower part of the left chest with the result that the hæmoptysis was checked. The patient was ultimately discharged in a much improved condition on 9th October, 1936.

Case II.—S. P. S., male, aged 22, admitted on 26th January, 1936, for the treatment of fever, cough and pain on the left side of the chest. X-ray examination revealed opacity of the left chest which turned out to be an empyema. The sputum was positive. Three pints of pus were aspirated and later on partial rib resection and intermittent irrigation of the pleural cavity with Dakin's fluid were done as advised by Lieut.-Col. F. J. Anderson, F.R.C.S., I.M.S., the Professor of Clinical Surgery, Medical College Hospitals, Calcutta. Temperature subsided and the patient was much improved.

On 28th March, 1936, the patient developed chicken-pox and high fever which subsided on 13th April. The patient started profuse hæmoptysis from 7th June. He was treated with diamorphine hydrochloride, hæmostatic serum, calcium, five intravenous injections of congo red (1 per cent), 10 c.cm. each, but the hæmorrhage continued till 250 c.cm. of air were injected subcutaneously

PULMONARY TUBERCULOSIS AND KALA-AZAR: A FATAL COMBINATION

By L. EVERARD NAPIER, M.R.C.P. (Lond.)

Acting Professor of Tropical Medicine.

(From the Calcutta School of Tropical Medicine)

It has always been the teaching at the Calcutta School of Tropical Medicine that, in cases of kala-azar in which there is any secondary infection or disorder that demands treatment, the treatment for kala-azar should be given first. This applies particularly in the case of hookworm and other helminthic infections. We have been unconvinced by the statement found in textbooks that these helminthic infections interfere in any way with the efficacy of the specific antimony treatment, and in cases 'resistant' to treatment we have never found that the removal of the worms made the sub-

(Continued from previous page)

in the back; this controlled the hæmoptysis. The patient was ultimately discharged in a much improved condition on 2nd October, 1936.

Case III.—S. C. B., male, aged 24, admitted on 14th August, 1936, with profuse hæmoptysis of five days' duration. X-ray examination revealed infiltration and exudation of the middle and lower fields of the left lung. The sputum was positive. Treatment with morphia, calcium, and hæmostatic serum lessened the hæmoptysis in quantity in three days' time, but it again became copious whereupon subcutaneous injection of 250 c.cm. of air was given on the left side of the back of the chest; this was repeated (the same quantity) three days later, with the result that the hæmoptysis was checked.

Case IV.—P., male, aged 20, admitted on 8th July, 1936, with a history of slight fever, cough and recurrent hæmoptysis—the last attack being one and a half months prior to admission. X-ray examination revealed infiltration and cavitation of the sub-apical region of the right lung. The sputum was positive. On 4th August the patient started getting hæmoptysis again and was treated on the usual lines, but without any result. On 7th August 250 c.cm. of air were injected subcutaneously in the back with the result that the hæmoptysis was checked.

Case V.—P. K. D., female, aged 24, admitted on 28th May, 1936, for fever and hæmoptysis. The hæmoptysis dated from 12th May and persisted profusely till her admission. As she was in very low condition, no x-ray examination could be done. The sputum was positive. She was treated with diamorphine hydrochloride, calcium, hæmostatic serum and ten injections of congo red (1 per cent), 10 c.cm. each, intravenously. As these did not check the hæmorrhage, a subcutaneous injection of 250 c.cm. of air was given, which temporarily checked the hæmorrhage. Unfortunately broncho-pneumonia followed the aspiration of blood. Thenceforward the patient suffered from weekly bouts of hæmoptysis. It was not possible to inject any more air subsequently on account of the persistence of the emphysema, extremely low general condition due to broncho-pneumonia, and pain. The patient ultimately expired on 25th June, 1936.

It will thus be apparent that the subcutaneous emphysema treatment could not be fully tried in this case.

REFERENCE

Gonzalez de Vega, N., and Castilla Perez, D. (1935). *Siglo Medico, Madrid*. Vol. XCV, p. 485. (Abstracted—*Journ. Amer. Med. Assoc.*, Vol. CIV, p. 2218.)

sequent course of treatment more effective. On the other hand, after a course of antimony treatment the patient is much better able to stand the anthelmintic treatment, whereas serious collapse and even death has followed the administration of chenopodium and carbon tetrachloride in the usual doses in a debilitated kala-azar patient.

Another example is pyorrhœa; local medical treatment for this should be given, but removal of a few teeth may lead to uncontrollable hæmorrhage from the gums. Some years ago we lost two patients through over-vigorous dental treatment: having gained our experience in the first case, in the second we had issued a special warning which was ignored and six teeth removed.

We do not of course mean to imply that these concomitant infections are unimportant: on the contrary they often require vigorous treatment before the patient is restored to full health. Further, in the case of intestinal and some pulmonary complications it is advisable to give symptomatic treatment at the same time, but the specific antimony treatment should not be postponed on account of the presence of these complications, nor in order that they may be treated first. The best example of all is cancer oris which is an indication for immediate specific treatment if the patient's life is to be saved.

There is, however, one disease in which the antimony treatment itself seems to exert a malign influence on its course, namely, pulmonary tuberculosis. We have frequently observed that, when kala-azar and pulmonary tuberculosis co-exist, antimony treatment has little or no effect on the symptoms—fever and splenic enlargement—and that, on the other hand, the lung lesions undergo rapid extension when antimony is given.

The notes on two cases are given to illustrate this point:—

Case I.—A. M., male, Bengali, Hindu, aged 20 years, was admitted into the hospital attached to the Calcutta School of Tropical Medicine with a history of irregular fever for two years; during this period he had been apyrexial for six months but the fever had now returned. His spleen had been enlarging gradually during the last year. He had a chronic cough and suffered from indigestion.

He was thin, weight 84 pounds, anæmic in appearance and generally debilitated. His spleen was four inches below the costal margin, and his liver was palpable. His gums were spongy and tended to bleed. Nothing abnormal was noted in his heart, except an increased rate of 108. When examining his lungs, the admitting officer noticed nothing abnormal. His temperature was of a moderately high remittent type; his respirations were 26 per minute. His aldehyde test was strongly positive. The Wassermann reaction was also positive. A spleen puncture showed the presence of leishmania.

The patient was put on to a course of neostibosan, on alternate days; the first dose was 0.15 gramme and all subsequent doses 0.25 gramme. This modified dosage was given in deference to his debilitated condition.

After the first few injections exacerbation of the lung symptoms was noticed and his lungs were re-examined.

Case I.

Case II.

Fig. 1.—Antero-posterior view.

Fig. 2.—Right oblique view.

Fig. 3.—After removal of cyst and phrenic evulsion,
leading to recovery.

The note at the right apex was found to be dull and fine crepitant râles could be heard all over the upper lobe. The sputum was examined and tubercle bacilli found.

Meanwhile, he had received twelve injections of neostibosan—total dose 2.9 grammes. This course of injections had no effect whatsoever on his temperature which was still a remittent fever reaching 102°F. daily. His spleen appeared to be slightly reduced in size. His cough was worse and an examination of the lungs suggested that the tuberculous process was extending.

An x-ray examination of the chest (plate XVI) showed the following conditions: 'Infiltration and cavitation right upper field; right basal pleurisy'.

In both instances the antimony treatment appears to have caused an acceleration of the tuberculous process.

In the first case there is some evidence that the leishmania infection was cured, but in the second the presence of the tuberculous infection appears to have exercised an inhibitory effect on the action of antimony.

We have unfortunately no actual radiographical evidence of this rapid extension, but

CHART

X-ray report

A second spleen puncture was done and no leishmania was found in the smear. This suggests that the antimony had acted specifically on the leishmania infection, but had, on the other hand, lighted up the lung lesions.

Case II.—P. M., a boy, aged 7 years. He gave a history of irregular fever for six months, a cough, irregular motions, an enlarged spleen and liver, oedema of the feet, and anaemia.

Examination of the lungs showed scattered coarse râles and rhonchi over both lungs. The spleen was just palpable. His temperature was of a high intermittent type rising to 103°F., pulse 140, and respirations 28.

Laboratory examinations showed:—*Entamoeba histolytica* in the stools; Wassermann reaction—moderately positive; aldehyde test +++; and leishmania in the peripheral blood. No tubercle bacilli were found in the sputum.

He was put on neostibosan intravenously; the first dose was 0.05 gramme, the second 0.1 gramme, and subsequent doses 0.15 gramme on alternate days—a total of 1.65 grammes.

His cough became worse and examination of the chest showed scattered fine crepitant râles all over both lungs. The injections had no effect on his temperature which remained high intermittent with a single daily rise (see chart). The spleen remained just palpable.

At this point we found out that he was the brother of case I and despite the negative sputum findings we focused our attention on his chest again. The physical examination was suggestive and a skiagram (plate XVI) was taken; the report on this was as follows:—'Extensive infiltration both lungs'.

A culture of the peripheral blood showed leishmania still present.

Each patient was taken to his home and both are reported to have died within a few months.

in the first case the lung lesions were overlooked during physical examination at the time of admission, which became very obvious a few weeks later (though it is inconceivable that the extensive lesions seen in the skiagram could have developed in so short a time), and in the second the nature of the physical signs changed very rapidly. In both instances there was exacerbation of the symptoms.

There is, however, only one specific for kala-azar and so one is placed between the devil and the deep sea. Though in neither instance quoted was the usual course of daily injections given nor was the dosage the maximum dose for the age of the patient, it does seem possible that by reducing the dosage in these cases, one might cure the kala-azar without producing the unfavourable reaction. In any case this procedure would seem to offer the only chance of success, as at this stage it is probably very seldom that kala-azar undergoes spontaneous cure, and, on the other hand, it is unlikely that one could stop the tuberculous process in a patient in which the leishmania infection was active.

We have repeatedly observed this detrimental action of antimony in phthisis. These two cases illustrate this observation very well, but they were also of special interest, in that the patients were both members of the same family and were admitted into different wards in our hospital at about the same time.

A CASE OF HYDATID CYST OF THE LUNG, WITH POST-OPERATIVE TUBERCULOUS INVOLVEMENT

By A. C. UKIL, M.B., M.S.P.E. (Paris), F.S.M.F., F.N.I.

and

S. K. GANGULI

(From the Department of Chest Diseases, Medical College Hospitals, Calcutta)

Clinical history.—A Hindu male, aged 32 years, a dog lover, complained of irregular low fever (99°F. to 100°F.), heaviness of the right chest and cough which increased on trying to lie down on the right side, and recurrent small hæmoptysis for three months. There was no anorexia nor emaciation. As regards previous history, it transpired that he was once treated for cervical adenitis at the age of 12 years. He was being treated for pulmonary tuberculosis by a physician outside. He came under our observation in August 1934.

Physical examination.—The right side of the chest showed loss of resonance from the level of the fourth rib downwards. On auscultation, nothing beyond some diminution of breath sounds was noticed. Sputum examination was repeatedly negative for tubercle bacilli.

X-ray examination—showed a circular opacity, with a regular margin, about the size of a tennis ball above the diaphragm, but not adherent to its surface. The left lung showed a small healed tuberculous lesion at the apex. A provisional diagnosis of hydatid cyst of the lung was made on the strength of this evidence. To confirm the provisional diagnosis, a complement-fixation test was performed at the Indian Institute for Medical Research, using the hydatid fluid from diseased sheep's liver as antigen. This proved to be strongly positive. The Wassermann reaction was negative. A differential count of blood showed an eosinophilia of 7 per cent.

On the 15th October, the patient had an acute attack of pleurisy when it was decided, in consultation with Lieut.-Col. F. J. Anderson, I.M.S., of the Medical College Hospitals, to operate on him in two stages. The first stage of the operation was done by Col. Anderson on 20th October by removing the anterior portions of the fourth and fifth ribs on the right side. The hydatid cyst was located by puncturing the cyst wall with a syringe; some fluid was taken out for microscopic examination (which showed echinococcus hooklets) and 5 c.cm. of 40 per cent formalin was injected into the cyst to kill the brood capsules and scolices. The operation was performed under local anæsthesia (novocaine 2 per cent), aided by a few whiffs of ether. The space between the visceral and parietal pleura was packed with corrugated drainage sheet to induce adhesions to form. After eight days, when it was found that the adhesions had walled off the site, the second stage of the operation was undertaken under local anæsthesia, aided by gas and oxygen. It was noticed that on account of the rise of the diaphragm after the first operation, the cyst was pushed much higher up than its original position before operation. A bloodless operation was done with the aid of the diathermy knife and the cyst (both ecto- and endo-cyst) was completely removed.

The wound healed, except for a slight discharge from the previous track of the drainage tube, at the end of one month, but a slight afternoon temperature still persisted. A skiagraphic examination showed a diminution in the size of the area covered by the cyst, but a worrying incident occurred at this stage; the sputum

showed a few tubercle bacilli. This was in February 1935. With right phrenic evulsion and gold therapy (sanocrysin), carried out at the Madanapalle Sanatorium, the tubercle bacilli disappeared from the sputum and the patient made a steady recovery. The patient has been examined since and is keeping well.

In our opinion, the tubercle bacilli detected in the sputum after the operation were probably due to the injury of a tuberculous gland near the wall of the cyst. No serious damage to lung tissue occurred, probably because of a high degree of allergy on the part of the patient and also owing to the timely compression of the affected area by phrenic exairesis.

In August 1934, Drs. Tulsi Dass and Pirthichand (*Indian Medical Gazette*, August 1934, pp. 448-449) reported a case of hydatid cyst of the lung where, thinking that they were dealing with a case of pleural effusion, anaphylactic shock occurred after aspiration and immediate operation had to be performed in a boy of 14. This was followed by recovery. We believe this is the first reported case where the cyst has been successfully removed without leakage.

The skiagrams before and after the operation are given (plate XVII, figures 1, 2 and 3).

NOTICE

On account of shortage of space three papers which should have been included in this number have been held over and will be published in a subsequent number. The titles are given below:—

(1) A Short Note on the Diagnosis of Pulmonary Tuberculosis. By D. R. Dhar, M.B., D.T.M. (Cal.), M.R.C.P. (Lond.).

(2) Investigations into the Blood Picture, specially of Leucocytes, in Pulmonary Tuberculosis. By B. Jayaram, M.B.

(3) A Case of Pulmonary Tuberculosis, Complicated with Syphilis. By A. C. Ukil, M.B., M.S.P.E. (Paris), F.S.M.F., F.N.I.

Indian Medical Gazette

APRIL

THE SPECIAL TUBERCULOSIS NUMBER

THE question of starting a tuberculosis journal has often been mooted. India is a large country and the problem of tuberculosis is sufficiently important to justify an examination of that question.

There would be some advantage in collecting together, from time to time, under one cover, authoritative articles and reports of work done by specialists in this country on this vital subject, in order that they might be readily available to all tuberculosis workers who would thereby be saved the trouble of searching through a number of medical journals.

There is, on the other hand, one very great objection to such a scheme, and the same objection is applicable to the case of all specialist journals—it does collect together all papers on the subject to the advantage of the specialist who will naturally subscribe to the journal on his own subject, but it also attracts to itself articles that would otherwise be distributed in various general medical journals and it withdraws from the general practitioner the advantage of reading such articles, as the average practitioner can seldom afford more than one journal.

The distribution of a specialist journal is always limited compared with that of a journal that caters for the general practitioner. Consequently, the starting of a specialist journal, by segregating rather than disseminating papers written by specialist workers, may defeat the avowed object of such a journal, namely, the furtherance of the study of the special subject.

This was the view taken by the committee of the King George Thanksgiving (Anti-Tuberculosis) Fund when they approached us and asked if we would be prepared to publish a special tuberculosis number of the *Indian Medical Gazette*.

A special number of this kind provides all the advantages of a specialist journal to the specialist, and at the same time, as it is distributed to the four thousand regular readers of the *Gazette*, the attention of a large number of practitioners in all parts of India is drawn to the subject.

The Secretary of the King George Thanksgiving Fund, Dr. A. R. Mehta, undertook to circulate tuberculosis workers in India advising them of our intention to publish this special number. The response has been very satisfactory, almost embarrassing, and although we have excluded all other matter we have had to increase the size of the number very considerably to accommodate the articles selected for

publication, and even then at the last minute we have had to hold over one or two for subsequent numbers.

The Editor has been assisted by a small but representative editorial committee, consisting of Drs. A. C. Ukil, A. R. Mehta, C. Frimodt-Møller, and M. Kesava Pai, who have gone through all the papers submitted and have selected certain of them for publication. This committee, however, wishes it to be made quite clear that approval of these papers as suitable for publication does not necessarily carry with it approval of the principles enunciated therein. They do not wish the number to represent only their own points of view but rather those of all workers in India, who by their position and achievements can be considered competent to express an authoritative opinion.

The Editor takes this opportunity of thanking the individual contributors, the Secretary of the King George Thanksgiving (Anti-Tuberculosis) Fund, the editorial committee and Dr. A. C. Ukil in particular to whom on account of his presence in Calcutta we frequently referred for important decisions, and the publishers, who have generously increased the size of the number and included a large number of illustrations without extra cost to subscribers, for making the special number the success which he feels can be claimed for it.

THE TUBERCULOSIS PROBLEM IN INDIA

IN considering the tuberculosis problem in India, perhaps one of the most important points to realize, and one that has only been fully appreciated as yet by a few workers, is that the problem is a *new* one. By this we do not mean to imply that tuberculosis is a new disease or even that it is a recent arrival in this country. Tuberculosis has claimed its victims in India for the last twenty-five centuries at least, as the disease was described by Sushruta, but even to-day it is apparently not as prevalent as it is in many western countries. Then why, it will be said, is it a major public health problem? There are two reasons; one is to be found in the word *apparently*—we do not really know the degree of infection of the population—and the second is that such evidence as exists points unequivocally to the fact that the disease is extending rapidly, and has already reached the threshold value of a public, as distinct from an individual, health problem. This much the public health authorities have in recent years been prepared to concede, and in his 1934 report the Public Health Commissioner with the Government of India says:—

'The wide distribution of tuberculosis of recent years must in a considerable measure be due to increase of urbanization and the environmental factors associated therewith, producing overcrowding and other conditions which predispose to this disease. The present position

would appear to be that, whereas our towns are heavily infected, and their residents tuberculized to some extent, the rural populations for the most part have not yet experienced the full force of the disease. If this assumption be correct, we must anticipate a much greater spread of tuberculosis among the rural population which will be facilitated by the rapidly increasing means of communications from town to village and from village to village.

Our data in regard to the incidence of tuberculosis are lamentably deficient. Only in some urban centres has it been practicable to make the disease notifiable. There is no use in introducing compulsory notification unless it can be enforced in practice, and there are many obstacles in the way, including paucity of qualified medical practitioners, the *purdah* system, ingrained prejudice against hospitals, and the tendency to conceal disease until the development of symptoms make concealment no longer possible. Generally speaking, the population of India is highly susceptible to tuberculosis and among most of them the disease takes a virulent form and runs a rapid course. Public health officers may well sigh in despair of tackling this vast problem satisfactorily within the life-time of the present generation. Environmental sanitation in India is definitely backward, and in particular the housing problem is exceedingly difficult. Many urban areas have bad or indifferent building by-laws and these, such as they are, tend to be inadequately enforced. We are witnessing to-day in many towns the creation, year by year, of housing conditions favourable to the rapid spread of tuberculosis. Until this problem is dealt with, we shall continue to create new slums within our towns and to add to the magnitude of the tuberculosis problem. First and foremost, the problem resolves itself into one of improving housing in urban areas with all that this connotes in the way of space, sunlight and fresh air. To tackle the problem from any other aspect than this is to begin at the wrong end. It is beyond the financial resources of the country to build hospitals and sanatoria to house our countless cases of tuberculosis, unless we can reduce markedly the number of fresh cases infected each year, by improvement of environmental conditions. Energetic propaganda is therefore required, particularly among the members of municipal committees and the like, to impress upon them the importance of improved housing in their towns and the provision of parks and playgrounds.

The importance of good nutrition in the prevention of tuberculosis cannot be overstressed. This however is a problem by itself. Here it may only be noted that there is evidence of increased attention being paid to this vitally important subject.

Last year the Director-General, Indian Medical Service (Sir John Megaw), on the basis of data collected by him from medical officers and others throughout India, reported that there are probably two million cases of tuberculosis in India.

There are two main factors in any disease—the seed and the soil; except that the proportion between the human and bovine types is not the same, the seed—as far as we know, but even then there is room for more knowledge—is much the same as in other countries, but the soil is entirely different from that anywhere in the world. The whole problem is therefore quite outside past human experience and is consequently an entirely new one.

It may be claimed that most of the conditions existent in India also exist in other countries, and it is true that each individual factor governing the epidemiology is not peculiar to India, for example, the climates that are found here are also found in other countries, there are

other countries in which the population has an equally low nutritional status and where the majority sleep huddled together in small and ill-ventilated dwellings, where the proportion between the urban and the country populations is the same, and is moving in the same direction at the same rate with the advance of industrialization, where aboriginal populations mix with civilized populations, and where above all the economic question overshadows everything. But nowhere else in the world do these factors come into play in exactly the same way as they do in India, as a whole or in its numerous parts. Therefore, knowledge gained in other countries must be applied here with the utmost caution, until by scientific investigation it has been shown that the same epidemiological state does actually exist, and we must not assume that, because one set of environmental factors led to a certain state of affairs in Massachusetts, they will do the same in Mandalay.

Well-planned and standardized epidemiological surveys, and clinical, pathological and bacteriological investigations in different parts of the country are essential if we are to gain this knowledge, and, with all the attention that is being focused on this tuberculosis problem, there is little evidence that this fact is fully appreciated.

The public demand sanatoria and dispensaries where their children, their brothers and their cousins can be sent for treatment, the public-health authorities demand health visitors to seek out the patients in their homes, education and propaganda, and regulations to enforce notification and isolation, to prevent overcrowding and bad housing, to improve the food supply, and prevent the sale of infected milk. These are all excellent in their way—sanatoria and dispensaries are essentials, but if the whole revenue of the country were spent in building and running them we should still not have solved the tuberculosis problem; education and propaganda are probably the most valuable of all means of combating the disease, but are we sure that we know exactly what to teach the people; and laws and regulations are also necessary, but are liable to be translated too literally from those of other countries where conditions are different and again we come back to the necessity for exact knowledge in matters on which we are only guessing.

The position can be summarized by saying that though both medical relief and direct preventive measures are essential in an anti-tuberculosis campaign—in this or in any other country—in this country in particular organized research, both in the field and in the laboratory, must be included in any comprehensive and progressive scheme for tuberculosis control.

L. E. N.

KING GEORGE THANKSGIVING (ANTI-TUBERCULOSIS) FUND

HISTORY

OURS is a country where things move rather slowly and the setting up of a voluntary national organization to fight tuberculosis proved no exception to the rule. It was nearly a generation ago in 1910 that Sir Pardey Lukis, the then Director-General of Indian Medical Service, addressed the Government of India and stressed the need for a concerted action to fight tuberculosis. In 1914-16 as a direct outcome of the resolutions of the All-India Sanitary Conferences, Dr. Lancaster was specially deputed by the Indian Research Fund Association to investigate if the increase in tuberculosis was real or apparent. He visited all the provinces and nearly all the big cities and formed the view that tuberculosis was on the increase in India. The account of his tour and the reasons for his opinion are published in a large volume.

Major-General Sir John Megaw wrote in 1933 'Tuberculosis is well known to be exceedingly prevalent in the cities and large towns. The disease is increasing steadily, and rather rapidly The estimate of just over two million cases of tuberculosis in India as a whole is probably much too low. Every large town is known to be very heavily infected'. Twenty years ago Dr. Lancaster came to the conclusion that the best chance of success lay in establishing a closer co-operation between Government enterprise and voluntary effort. He suggested the formation of an all-India anti-tuberculosis association.

In 1927, Lord Irwin, the Viceroy and Governor-General of India, realized the gravity of the problem and wished to form a central organization to give the required lead to the country on the lines of the National Association for Prevention of Tuberculosis in Great Britain. However, on account of the political situation and financial depression he deferred a nation-wide appeal to a more opportune time.

The opportunity for setting up a central organization came in 1929 when the merits of the various schemes submitted for utilization of the King George Thanksgiving Fund, which amounted to Rs. 9,50,000, were considered. After the fullest consideration the advisory committee formed for the purpose recommended that an anti-tuberculosis scheme was one that was most likely to be of real service to India. It was the result of this that the King George Thanksgiving Fund Anti-Tuberculosis Committee was formed and the central office established in 1931.

PROGRAMME OF WORK AND ACTIVITIES

The tuberculosis problem is not only a medical but a social problem as well. Hence the anti-tuberculosis campaign resolves itself into—

(1) The removal of ignorance by education of the public in the causes and prevention of the disease.

(2) Improvement in the conditions of living, e.g., town planning, better housing, sanitary improvements, etc.

(3) The removal of certain social customs and vices.

(4) The provision of tuberculosis dispensaries for early diagnosis of cases, contacts, etc.

(5) Establishment of sanatoria, hospitals, preventoria, colonies, etc.

If we had unlimited resources and powers we could undertake all the above measures. But the annual income is about Rs. 53,000 and consequently the activities have to be extremely restricted.

One thing realized right from the beginning was that for a long time hospitals and sanatoria attracted most if not all the attention of the public and the authorities to the exclusion of other measures. There is no doubt that these institutions serve a very useful purpose by—

(1) Arresting and curing the disease.

(2) Teaching the hygienic mode of living.

(3) Segregating the source of infection.

But whatever the achievements and advances made in the surgical and medical treatment of tuberculosis sanatoria cannot solve the problem. Their work for the individual is admirable. They give him a better chance of life, but from the social standpoint this work will always be incomplete. Treatment plays an important part, but the salvation of the community lies in prevention.

Practically all the activities of the Fund are directed towards prevention of tuberculosis. We have set ourselves to organize anti-tuberculosis committees in the provinces as well as in the Indian states, to educate the people about causes and prevention of tuberculosis and to create a public conscience so that efforts may be made in all directions to fight the disease.

We have now 16 anti-tuberculosis committees in the country. These committees include public-spirited men and women of all shades of opinion, members of the education and public-health departments and non-officials interested in the welfare of the people in general and in the anti-tuberculosis campaign in particular.

The chief aim of the Fund is to organize an educational campaign and with this end in view we prepare and publish suitable material for distribution and utilization by various agencies and departments engaged in the prevention and control of tuberculosis. We have now a very large amount of propaganda material in the shape of charts, posters, leaflets, films, slides, etc.

Our three series of picture posters on 'Causes, Prevention, and Signs and Symptoms' are extremely attractive and instructive. We have several films on tuberculosis with Urdu and

Hindi titles which have been exhibited at a large number of places in various provinces and stalls. A propaganda cinema lorry has been fitted up at headquarters, which has done extensive touring in the North West Frontier Province, the Punjab and the United Provinces.

The propaganda and educational campaign should be a sustained one and should go side by side with the establishment of either special tuberculosis hospitals or tuberculosis wards attached to the existing hospitals. These serve a very useful purpose not only from the treatment point of view but also for segregating tuberculous cases who are the sources of infection. But, no tuberculosis scheme can be complete without the establishment of tuberculosis clinics and dispensaries.

A tuberculosis dispensary is a specialized institution, the foundation of tuberculosis work. It is perhaps a misnomer as the word presupposes a place for doling out medicines. It is here that the patients are examined, the disease diagnosed and advice given. It is from the dispensary that the homes are visited, contacts are examined and cases are discovered. Its main function is education and epidemiological survey, and its essential agents are the doctor and the health visitors. The Fund committee helps to start such dispensaries and I am glad to record that the value of tuberculosis dispensaries is being realized and the Governments of

Bombay, Central Provinces and Bihar are going to set up such clinics in many of their big towns.

I do not propose to go into the details of many other activities of the Fund, *e.g.*, our relations with the International Union against Tuberculosis, securing of foreign scholarships, surveys conducted by its help, etc., which can be seen from our annual reports that are published each year.

The Fund has completed its five years' existence and against many odds and handicaps has proved its usefulness.

It has been able to focus the attention of the public and the authorities who are beginning to realize tuberculosis as a major public-health problem.

I sincerely hope that the Fund one day will blossom into a full-fledged national association free to expand its activities and take its rightful place alongside other independent national tuberculosis associations, *e.g.*, in U. S. A., Great Britain, France, Germany, etc.

These associations are recognized by their respective governments as being of great utility. The State endows them with the status of incorporated and registered societies and even delegates its powers to them and the day may not be far when there may be a national insurance against tuberculosis.

A. R. MEHTA.

Medical News

POST-GRADUATE COURSES UNDER THE AUSPICES OF THE KING GEORGE THANKSGIVING (ANTI-TUBERCULOSIS) FUND

ONE hears lamentations from medical superintendents of various sanatoria and from other experts that the vast majority of tuberculosis cases that go to them are in an advanced stage of the disease. Tuberculosis is no longer considered an incurable disease. Cases diagnosed early can be adequately treated and the disease arrested. The failure of the young practitioner to diagnose the disease may be attributed partly to the defect in the medical curricula where more attention is devoted to diseases like plague, cholera and smallpox, which even put together are responsible for fewer deaths than tuberculosis. Not only that enough importance is not given to the diagnosis and treatment of tuberculosis, but the causes and prevention of tuberculosis also are neglected. Moreover, the facilities for seeing special work in tuberculosis exist in sanatoria which are well away from the teaching institutions and it is thus that some of our young physicians who are the ones with whom the tuberculous cases first come in contact are not well equipped to help in the fight against tuberculosis. This was realized by the King George Thanksgiving (Anti-Tuberculosis) Fund and efforts have been made to organize intensive post-graduate courses at important centres. So far three such courses have been held in Calcutta where the best facilities for such training exist. These courses have been held at the All-India Institute of Hygiene and Public Health, Calcutta, with the full support and co-operation of the authorities of the Institute, the Medical College, Calcutta, and the Tuberculosis Association of Bengal to whom our thanks are due. The classes are limited to

25 candidates only as this is considered to be the maximum number that can be handled effectively for demonstration and clinical purposes. In selecting candidates various points are kept in view, such as age, qualifications, past experience in tuberculosis, and facilities for tuberculosis work after training, which is based on the recommending authorities; territorial distribution is also kept in view and our classes have included candidates from nearly all the provinces of British India and important Indian states.

For the last post-graduate course we received as many as 213 applications and the course was organized from 4th to the 29th January, 1937. The programme is given below in detail, which will show that within the period of a month as much knowledge of diagnosis, prevention and treatment of tuberculosis is given as is possible.

KING GEORGE THANKSGIVING (ANTI-TUBERCULOSIS) FUND (Indian Red Cross Society)

Programme of lectures and demonstrations for the post-graduate course in tuberculosis—3rd session, Calcutta, 4th to 29th January, 1937

Monday, 4th January. Welcome by Dr. A. R. Mehta at All-India Institute of Hygiene at 10 a.m. Opening address (The tuberculosis problem in India) by Dr. Sir Nilratan Sircar at All-India Institute of Hygiene at 10-15 a.m. King George Thanksgiving Fund, its history organization, functions, etc., by Dr. A. R. Mehta at All-India Institute of Hygiene at 11 a.m. Tubercle bacillus (lecture and laboratory work) by Dr. K. V. Krishnan at All-India Institute of Hygiene at 2 to 4 p.m.

Tuesday, 5th January. Epidemiology of tuberculosis, with special reference to India by Dr. A. C. Ukil at All-India Institute of Hygiene at 10 to 12 a.m. Pathology of tuberculosis, including portals of entry of the tubercle bacillus by Dr. K. V. Krishnan at All-India Institute of Hygiene at 2 to 4 p.m.

Wednesday, 6th January. Tuberculosis in infancy and childhood by Dr. A. C. Ukil at All-India Institute of Hygiene at 9 to 10 a.m. Demonstration and examination of cases (childhood type) by Dr. A. C. Ukil at Chest Department, Medical College Hospital, at 10 to 12 a.m. Pathology of tuberculosis (demonstration) by Dr. P. K. Sen at All-India Institute of Hygiene at 2 to 4 p.m.

Thursday, 7th January. Pulmonary tuberculosis in the adult by Dr. A. C. Ukil at All-India Institute of Hygiene at 9 to 10 a.m. Demonstration and examination of cases (adult type) by Dr. N. Mukerjee at Chest Department, Medical College Hospital, at 10 to 12 a.m. Laboratory methods in diagnosis and prognosis of tuberculosis (demonstration) by Dr. K. V. Krishnan at All-India Institute of Hygiene at 2 to 4 p.m.

Friday, 8th January. Pulmonary tuberculosis in the adult (contd.), by Dr. A. C. Ukil at Chest Department, Medical College Hospital, at 9 to 10 a.m. The interpretation of lung radiograms by Dr. A. C. Ukil at Chest Department, Medical College Hospital, at 10 to 12 a.m. Administrative and preventive aspects of tuberculosis and the organization of anti-tuberculosis work by Dr. A. R. Mehta at All-India Institute of Hygiene at 2 to 4 p.m.

Saturday, 9th January. Miliary tuberculosis by Dr. A. C. Ukil at All-India Institute of Hygiene at 9 to 10 a.m. Demonstration and examination of cases by Dr. N. Mukerjee at Chest Department, Medical College Hospital, at 10 to 12 a.m. Artificial pneumothorax rationale by Dr. K. N. De at All-India Institute of Hygiene at 2 to 4 p.m.

Monday, 11th January. Certain complications of pulmonary tuberculosis (contra-lateral lesion, hæmoptysis, pleural effusion, spontaneous pneumothorax, laryngitis, enteritis, diabetes, pregnancy) by Dr. A. C. Ukil at Chest Department, Medical College Hospital, at 9 to 11 a.m. Demonstration and examination of cases by Dr. A. C. Ukil at Chest Department, Medical College Hospital, at 11 to 12 a.m. Allergy and immunity in tuberculosis by Dr. A. C. Ukil at All-India Institute of Hygiene at 2 to 3 p.m. Microscopic demonstrations by Dr. Guha Thakurta at All-India Institute of Hygiene at 3 to 4 p.m.

Tuesday, 12th January. Differential diagnosis of pulmonary tuberculosis by Lieut.-Col. E. H. Vere Hodge at Lecture Gallery, Medical College Hospital, at 9 to 10-30 a.m. The value of radiology in the diagnosis of lung diseases by Dr. S. G. Galstaun at X-ray Department, Medical College Hospital, at 10-30 to 12 a.m. The rôle of general practitioner in the control of tuberculosis by Dr. A. R. Mehta at All-India Institute of Hygiene at 2 to 3 p.m. Tutorial talk by Dr. A. R. Mehta at All-India Institute of Hygiene at 3 to 4 p.m.

Wednesday, 13th January. Climate in tuberculosis by Dr. A. R. Mehta at All-India Institute of Hygiene at 9 to 10 a.m. Routine treatment at a dispensary clinic at Chest Department, Medical College Hospital, at 10 to 12 a.m. Tutorial talk by Dr. A. C. Ukil at All-India Institute of Hygiene at 2 to 4 p.m.

Thursday, 14th January. Operation of thoracoplasty—its applications and technique by Lieut.-Col. F. J. Anderson at P. W. Hospital at 10 to 12 a.m. The treatment of certain complications of pulmonary tuberculosis (hæmoptysis, pleural effusion, spontaneous pneumothorax, laryngitis, enteritis, diabetes, pregnancy) by Dr. A. C. Ukil at All-India Institute of Hygiene at 2 to 4 p.m.

Friday, 15th January. Heliotherapy in the treatment of tuberculosis by Dr. A. C. Ukil at All-India Institute of Hygiene at 9 to 10 a.m. The treatment of certain complications of pulmonary tuberculosis (hæmoptysis, pleural effusion, spontaneous pneumothorax, laryngitis, enteritis, diabetes, pregnancy) by Dr. A. C. Ukil at Chest Department, Medical College

Hospital, at 10 to 11 a.m. Bronchoscopic drainage by Dr. S. Roy at Ear, Nose and Throat Department, Medical College, at 11 to 12 a.m. Tuberculosis survey and the arranging of statistical material by Dr. R. B. Lal at All-India Institute of Hygiene at 2 to 4 p.m.

Saturday, 16th January. Demonstration in the tuberculosis ward, Medical College Hospital, by Lieut.-Col. E. H. Vere Hodge at Medical College Hospital at 9 to 10 a.m. Demonstration and examination of cases by Dr. N. Mukerjee, Chest Department, Medical College Hospital, at 10-30 to 12 a.m. Tutorial talk by Dr. P. K. Sen at All-India Institute of Hygiene at 2 to 4 p.m.

Monday, 18th January. Differential diagnosis of chest diseases through radiogram by Dr. K. P. Sen at All-India Institute of Hygiene at 9 to 10 a.m. Demonstration and examination of cases at Chest Department, Medical College Hospital, at 10 to 12 a.m. Rationale of phrenic evulsion by Dr. K. N. De at All-India Institute of Hygiene at 2 to 4 p.m.

Tuesday, 19th January. Tuberculosis of lymph glands, bones and joints, skin and organs of special sense and methods of immobilization by splints, plasters, etc., by Lieut.-Col. F. J. Anderson at P. W. Hospital at 9 to 11 a.m. Organization of anti-tuberculosis dispensary by Dr. Mrs. C. O. Remfry at P. W. Hospital at 2-30 p.m.

Wednesday, 20th January. Dispensary routine conducted by Drs. J. N. Mitra and S. Mazumdar at various dispensaries of T. A. B. at 9 to 11 a.m. Dispensary registers and records conducted by Drs. J. N. Mitra and S. Mazumdar at various dispensaries of T. A. B. at 3 p.m. Health visits with tuberculosis health visitors conducted by Drs. J. N. Mitra and S. Mazumdar at various dispensaries of T. A. B. at 4 to 6 p.m.

Thursday, 21st January. Non-tuberculous conditions simulating pulmonary tuberculosis by Dr. N. Mukerjee at Chest Department, Medical College Hospital, at 9 to 10 a.m. Operation of phrenic evulsion by Dr. P. Chatterjee at Operation Theatre, Medical College Hospital, at 10 to 12 a.m. The rôle of the health visitors in the prevention of tuberculosis, his training and equipment by Dr. Mrs. C. O. Remfry at All-India Institute of Hygiene at 3 p.m. Health visits with tuberculosis health visitors by Drs. J. N. Mitra and S. Mazumdar at 4 to 6 p.m.

Friday, 22nd January. Demonstrations at the Jadabpur Tuberculosis Hospital by Visiting Staff of the Hospital at Jadabpur, East Bengal Railway, at 9 to 12 a.m. and at 2 to 4 p.m.

Saturday, 23rd January. Demonstrations at the Jadabpur Tuberculosis Hospital at 8 to 12 a.m. and at 3 to 4 p.m. Tea party at Jadabpur, East Bengal Railway, at 4-30 p.m.

Monday, 25th January. The state and tuberculosis from the public health point of view by Dr. K. V. Krishnan at All-India Institute of Hygiene at 9 to 10 a.m. General principles of sanatorium treatment, including selection of cases, grading of exercises and after care by Dr. C. Frimodt-Møller at All-India Institute of Hygiene at 10 to 12 a.m. The position of medical treatment in pulmonary tuberculosis by Dr. C. Frimodt-Møller at All-India Institute of Hygiene at 2 to 4 p.m.

Tuesday, 26th January. Surgical treatment of pulmonary tuberculosis by Dr. C. Frimodt-Møller at All-India Institute of Hygiene at 9 to 10-30 a.m. Indications for and technique of lipiodol diagnosis in lung diseases by Dr. K. N. De at Chest Department, Medical College Hospital, at 10-30 to 12 a.m. Surgical treatment of pulmonary tuberculosis (contd.), by Dr. C. Frimodt-Møller at All-India Institute of Hygiene at 2 to 4 p.m.

Wednesday, 27th January. Results of sanatorium treatment in India, including after-histories by Dr. C. Frimodt-Møller at All-India Institute of Hygiene at 9 to 10 a.m. Physical methods in the treatment of tuberculous diseases by Dr. S. G. Galstaun at X-ray Department, Medical College Hospital, at 10 to 12 a.m. Prognosis in pulmonary tuberculosis by Dr. C. Frimodt-Møller at All-India Institute of Hygiene at 2 to 4 p.m.

Thursday, 28th January. Classification and charting of pulmonary tuberculosis by Dr. C. Frimodt-Møller at All-India Institute of Hygiene at 9 to 10 a.m. The choice of a method of treatment for pulmonary tuberculosis (a recapitulation) by Dr. C. Frimodt-Møller at All-India Institute of Hygiene at 10 to 11 a.m. The place of village settlements in the anti-tuberculosis campaign by Dr. A. C. Ukil at All-India Institute of Hygiene at 2 to 3-30 p.m. Group photo, All-India Institute of Hygiene, at 4 p.m.

Friday, 29th January. Demonstration and examination of cases by Dr. A. C. Ukil at Chest Department, Medical College Hospital, at 9 to 12 a.m. Tutorial talk at All-India Institute of Hygiene at 2 to 4 p.m.

Time may not be very far when this course could be expanded into a full diploma course but for such an ambitious scheme adequate staff will be required. Moreover, we cannot expect candidates to come forward for the diploma course unless and until opportunities are offered by various local bodies to avail themselves of such trained people.

A. R. MEHTA,
Organizing Secretary,
King George Thanksgiving (Anti-
Tuberculosis) Fund.

INTERNATIONAL UNION AGAINST TUBERCULOSIS

THE executive committee of the International Union against Tuberculosis, General Secretary Professor Fernand Bezancon, met in Paris on 9th January, 1937, at 2-30 p.m. The main object of this meeting was to come to a decision concerning the date of the tenth conference of the International Union which should have taken place in Lisbon in September 1936 under the chairmanship of Professor Lopo de Carvalho and which, owing to unforeseen circumstances, had to be adjourned.

It was agreed that the tenth conference should take place in September 1937, either at the beginning of the month, should it be possible to meet in Lisbon, or at a date to be decided later should the conference have to be held in another city.

In their wish to pay due regard to the active and intelligent endeavours of their Portuguese colleagues who, under normal conditions, would have been entitled to expect a most successful meeting, the members of the committee expressed the hope that the conference could take place in Lisbon next September, the final decision to be taken only towards the end of April or the beginning of May 1937.

The executive committee, on the other hand, decided that the eleventh conference of the International Union against Tuberculosis should meet in 1939, instead of 1938, in Berlin, subject to the statutory approbation of the next general assembly of the union.

The members of the committee were unanimous in expressing their gratitude to the Italian Government for having placed at the committee's disposal six scholarships at the Carlo Forlanini Institute in Rome.

They approved the Regulations of the Léon Bernard Memorial Fund according to which a prize shall be awarded every other year by the executive committee to the author of an essay on tuberculosis from a social point of view, written in French or in English.

Finally it was decided that the secretariat of the union would ask the councillor members in the different countries to select certain scientific questions which would be proposed for research and which might eventually be inscribed on the agenda of future conferences of the union.

THE WILLIAM GIBSON RESEARCH SCHOLARSHIP FOR MEDICAL WOMEN

MISS MAUD MARGARET GIBSON has placed in the hands of the Royal Society of Medicine a sum of money

sufficient to provide a scholarship of the yearly value of £292, in memory of her father, the late Mr. William Gibson of Melbourne, Australia. The scholarship is awarded from time to time by the society to qualified medical women who are subjects of the British Empire; and is tenable for a period of two years, but may in special circumstances be extended to a third year. The next award will be made in June 1937.

In choosing a scholar, the society will be guided in its choice 'either by research work already done by her, or by research work which she contemplates. The scholar shall be free to travel at her own will for the purpose of the research she has undertaken'.

There is no competitive examination, nor need a thesis or other work for publication or otherwise be submitted. The society has power at any time to terminate the grant if it has reason to be dissatisfied with the work or conduct of the scholar.

Applications should be accompanied by a statement of professional training, degrees or diplomas, and of appointments, together with a schedule of the proposed research. Applications must be accompanied by testimonials, one as to academical or professional status, and one as to general character. Envelopes containing applications, etc., should be marked on top left-hand corner 'William Gibson Research Scholarship' and should be addressed to Mr. G. R. Edwards, Secretary, Royal Society of Medicine, 1, Wimpole Street, London, W.1, and be received not later than Tuesday, 1st June, 1937.

INDIAN MEDICAL COUNCIL

MAJOR-GENERAL SIR F. P. CONNOR, *Kt.*, D.S.O., F.R.C.S. (Eng.), D.T.M. & H. (Eng.), L.R.C.P. (Lond.), K.H.S., I.M.S., Surgeon-General with the Government of Madras, has been duly nominated by the Government of Madras, under clause (a) of sub-section (1) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), as a member of the Medical Council of India, *vice* Lieut.-Colonel C. Newcomb, I.M.S., resigned.

In pursuance of the proviso to sub-section (2) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), the Governor-General in Council is pleased to nominate Major-General E. W. C. Bradfield, C.I.E., O.B.E., M.B., B.S. (Lond.), F.R.C.S. (Edin.), K.H.S., I.M.S., as President of the Medical Council of India with effect from the afternoon of the 13th February, 1937, *vice* Major-General Sir C. A. Sprawson resigned.

Lieut.-Colonel W. E. R. Dimond, L.R.C.P. & L.R.C.S. (Irel.), D.P.H. (Dub.), L.M. (Dub.), I.M.S., Assistant Director of Public Health, North-West Frontier Province, has been duly nominated by the Government of the North-West Frontier Province, under clause (a) of sub-section (1) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), as a member of the Medical Council of India, *vice* Colonel H. H. Thorburn deceased.

DELHI ANTI-MOSQUITO CAMPAIGN

THE SPRING MOSQUITO NUISANCE

EVERY year, during the early spring, there is throughout northern India an enormous increase in the number of culicine mosquitoes, commencing, as a rule, towards the end of March, reaching its greatest height in April, and dying away in May. Although they are harmless as regards the spread of malaria, these insects constitute a very real pest. In the worst years the plague is so bad that whenever an almirah is opened or a curtain shaken, a cloud of mosquitoes emerges.

The mosquito concerned breeds in any kind of stagnant water, whether clean or foul, favourite breeding places being stormwater drains with their catch-pits, sullage pits, disused wells, water in disused tins, earthenware pots, barrels, garden tanks and receptacles

POST-GRADUATE COURSE IN TUBERCULOSIS
KING GEORGE THANKSGIVING (ANTI-TUBERCULOSIS) FUND, 1937

of all kinds, sump-pits, quarry pits, water used in building construction, borrowpits, etc. It will breed in the cisterns and pans of water closets, and in the taps of bath-rooms, whenever these are not in daily use. When suitable breeding places are available, larvae are produced in enormous numbers so that a single small collection of water may produce many thousands of mosquitoes.

Unless the greatest care is taken, not only by the anti-mosquito staff but also by householders themselves, an annual recrudescence of the spring mosquito nuisance, in greater or less degree, is inevitable.

The public are invited to co-operate in the campaign by seeing that their cisterns and wells are mosquito-proof, that hydrants are not leaking, that anti-formicas, drains and gully traps are treated with phenyle solution twice a week, and that no receptacles which may hold water are left about on the roof or in the compound, either on the ground or suspended from trees. All broken ground in compounds should be levelled, and all rank vegetation removed.

A cheap and efficient anti-mosquito spray and an anti-mosquito pomade which is effective for several hours, are available at the Municipal Health Offices.

G. COVELL,

LIEUTENANT-COLONEL, I.M.S.

Director, Malaria Survey of India.

THE EPIDEMIC OF INFLUENZA

AN examination of the five numbers of the *Weekly Epidemiological Record* issued by the Health Section of the League of Nations Secretariat since the new year reveals the fact that while the epidemic of influenza in countries of Western Europe has been of fairly wide prevalence, it has been, with the exception of a few isolated cases, of a mild character. Mortality has at no time become more serious than that resulting from the 1932-33 epidemic; it cannot be compared with the gravity of the 1918-19 epidemic.

The present epidemic was first observed in the United States of America almost a month earlier than the appearance of epidemics in recent years. Here cases multiplied rapidly without, however, resulting in a serious rise in mortality. Toward the latter part of November and until the middle of December this 'benign' or mild form of the disease spread throughout North-Western Europe—in Germany, Czechoslovakia, the Netherlands and Denmark. Here the maximum rate of increase in mortality was reached in the third week of December, after which the rate diminished.

In Germany the greatest number of deaths from influenza was recorded in Berlin. Between 15th November and 19th December the general mortality rate reported weekly was 12.2, 14.2, 17.9, 20.1, and 20.7 per 1,000 inhabitants. Between 20th and 26th December, the number of deaths ascribed to influenza recorded in the 57 German towns of over 100,000 inhabitants fell from 535 to 512 and the general death rate per 1,000 inhabitants from 15.1 to 14.2.

Toward the end of December the epidemic invaded the British Isles, where it immediately assumed a more serious aspect. Four million cases appeared in and about London and in the south of England, followed quickly by a rise in the death rate. The general mortality rate between 27th December and 2nd January was 17.0 in the 122 large towns, 18.8 in Greater London, 22.1 in London itself, 22.1 at Bristol and 21.4 at Nottingham. The corresponding rates for the previous week were 10.8, 9.8, 9.0, 12.2 and 14.7, respectively.

It was observed that the majority of deaths occurred in cases of elderly persons. Of the 464 deaths attributed to influenza in London during the three weeks ending 9th January, 46.3 per cent occurred among persons over 65 years of age, and 5.2 per cent among persons of less than 25 years. During the 1933 epidemic 10.6 per cent of the deaths occurred among

persons of less than 25 years; in 1929, 8.8 per cent; in 1927, 10.1 per cent.

The epidemic increased in severity as January advanced, at the same time spreading from the south to the north of England, Scotland and Ireland (thus reversing the direction of the 1932-33 epidemic). During the week ending 9th January, the number of deaths attributed to influenza in the 122 large towns (England and Wales) reached 768 against 325; during the week ending 16th January, this figure rose to 1,100. The following week (ending 23rd January) saw a further increase to 1,137, but at a smaller rate—only 3 per cent. During this fortnight cases had been steadily decreasing in the south, but the epidemic was advancing in northern towns.

The *Weekly Epidemiological Record* reproduces the following report from the British Ministry of Health at the close of January: 'The epidemic continues to decline in the south of the country and is increasing in certain districts in the north. The age distribution of deaths shows a slight decrease in the proportion of deaths at ages over 65, but the proportion of deaths at ages over 65 continues to be more than 45 per cent. The general conclusion to be drawn is that the recrudescence will be less severe in its total effects than that of 1932-33. Some reserve must, however, still be maintained until the position in the north is clear'.

There have been very definite lags between the appearance of the outbreak in the various parts of Europe and even between various cities of the same country. Thus, while the peak mortality occurred in Berlin in the middle of December, it was reached at the end of December only in Königsberg, and in January in Breslau.

The peak of mortality occurred during the last week of December in Copenhagen, and during the first week of January in Amsterdam. In Poland the rates were not affected before the end of December.

No serious outbreak occurred in the Scandinavian and Baltic States, nor in Austria and Hungary. The disease was mild in Spain, France and Switzerland, as well as in Yugoslavia and Roumania.

LEAGUE OF NATIONS.

INFORMATION SECTION.

9th February, 1937.

THE PRACTITIONER

The Practitioner is probably the best-known journal of its kind in the world, and certainly in the English language. It does not publish reports on scientific investigation nor lengthy treatises, but short practical articles by authorities on their own special subjects. Such articles are invaluable to the practitioner in any country and therefore we are always tempted, and quite frequently fall to the temptation, to reproduce these articles almost verbatim in the columns of this journal, naturally with due acknowledgment of their source.

A few pages are devoted to short practical notes, usually on treatment, from other journals, case reports, reviews on recent books, and notes on new preparations.

The format of this journal has always been one of its most attractive features. The paper is stiff but not too heavy, the print is large and easy to read, and the book is of a convenient size to hold. At the beginning of this year the publishers altered the format slightly, making the page a little broader. Artistically they have achieved a great improvement and from a practical point of view there is something to be said for the slightly larger page.

We are glad to see that this change in the outward form of the journal is not accompanied by any other change, such as in the type of article contributed, as no change was necessary. We have now received the first two numbers of this year, and we have no hesitation in recommending wholeheartedly this journal to medical readers in this country.

Current Topics

The Tuberculosis Problem among Nurses in a Tuberculosis Sanatorium

By ERNEST S. MARIETTE, M.D., F.A.C.P.

(Abstracted from the *Tubercle*, Vol. XVIII, December 1936, p. 103)

TUBERCULOSIS is an infectious disease that is spread by contact with the patient's sputum rather than by contact with the patient himself and therefore the danger of infection diminishes with the effectiveness of the measures used in the disposal of sputum, etc. Owing to the more rigid observance of the measures of disposal of sputum in a sanatorium, the chances of infection here are less than elsewhere. Nurses when caring for tuberculosis patients for a long time are sure to get the infection. Afterwards they will behave according to: (1) whether they are tuberculin-positive or negative, (2) the length of time of exposure, (3) the connections from which the nurses are drawn, and (4) the nature and condition of the hospital. Only 2 to 10 per cent of those infected with tubercle bacilli fall ill. A tuberculin-positive nurse is less likely to develop serious and fatal tuberculosis as a result of caring for tuberculous patients than the tuberculin-negative nurse, though some believe that primary infection is benign but it makes the individual hypersusceptible to reinfection. According to laboratory experimentation, a mild infection increases the animal's natural resistance to exogenous reinfection when it occurs not sooner than four to six weeks after the first infection, i.e., after allergy has developed. In allergic animals, though the reaction becomes more acute at first after reinfection, it gradually subsides and becomes localized; of course, the smaller the dose of reinfection the better is the chance.

In this investigation all nurses were x-rayed at the beginning of their employment and yearly thereafter but later on they were x-rayed every three months. There were three groups of nurses: (1) supervising nurses, (2) general duty nurses, and (3) student nurses. The results of x-ray examinations of the above three groups of nurses are as follows:—

Group 1. Eighteen (16.5 per cent) had the adult type of tuberculosis at the beginning and another seven (8.3 per cent) subsequently developed the active, adult type of tuberculosis; there were two deaths in this group.

Group 2. Thirty-six (8.9 per cent) had the adult type of tuberculosis at the beginning and another 25 (6.2 per cent) subsequently developed the adult type of tuberculosis. This was considered inactive in eight, or 2 per cent, and active in 17, or 4.2 per cent, of the entire group; there were six deaths in this group.

Group 3. Sixty-eight (6.4 per cent) had the adult type of tuberculosis at the beginning and another 53 (4.9 per cent) subsequently developed the adult type of tuberculosis. This was considered inactive in 27 or 2.5 per cent and active in 26 or 2.4 per cent of the entire group; there were four deaths.

Taking the three as one group 122 or 7.7 per cent had the adult type of tuberculosis at the beginning and another 85 or 5.4 per cent subsequently developed the adult type of tuberculosis which was considered inactive in 35 or 2.3 per cent and active in 50 or 3.1 per cent. There were 12 deaths, five in the initial tuberculosis group and seven in those who developed tuberculosis subsequently. Thus, we see that 3.1 per cent of the nurses developed tuberculosis in the sanatorium. To minimize this the nurses should be

instructed how to protect themselves and the patients should be instructed to be careful about spitting, coughing and sneezing. The nurses should be x-rayed at the beginning and at regular intervals thereafter. Their working hours should be reduced and only tuberculin-positive nurses should be taken in, and if tuberculin-negative nurses are taken in they should be vaccinated with B. C. G.

Determination of the Artificial Pneumothorax Containing a Small Quantity of Gas

By E. SCHILL, M.D.

(Abstracted from the *Tubercle*, Vol. XVII, September 1936, p. 549)

To detect the presence of a small quantity of gas in the pleural cavity during the course of collapse therapy x-rays are usually used, but they are not always available, their frequent use is not safe, and, when the pleura is free from any adhesion, they may fail to demonstrate a small quantity of gas. The simple method of percussion over the areas of: (1) the costo-phrenic sinus, (2) the absolute cardiac dullness, and (3) Kronig's area, will help in the matter. Instead of percussing over the Kronig's area Frisch recommends percussion of the apex of the lungs, as given below. Draw a horizontal line between the spinous processes of the first and second dorsal vertebrae and mark on it two points, one on each side, three-finger breadths from the mid-line. Join these two points to a point marking the lowest limit of the scalp in the mid-line. Light percussion on these connecting lines from mid-line outwards enables one to detect a limit of resonance nearer the spine, since the air occupying the cone of the apical pleura is capable of greater expansion. The lower limit of resonance is on the affected side.

In left-sided pneumothorax a diminution of absolute cardiac dullness may be elicited. Gas disappears first from the costo-phrenic sinus, though adhesions of the two layers of pleura make this sign useless, moreover in a bilateral pneumothorax no comparison can be made. The patient lying on his side with the affected side uppermost often helps. Begin percussion a little above the lower limit of resonance and go downwards till dullness is reached, after percussing some time at this point resonance will reappear, go down till again dullness reappears and in this way in a case of pneumothorax you can reach the last rib.

A Study of the Pathology of Experimental Pulmonary Tuberculosis in the Rabbit

By E. M. MEDLAR

and

K. T. SASANO

(Abstracted from the *American Review of Tuberculosis*, Vol. XXXIV, October 1936, p. 456)

THE seed, the soil and the lapse of time after the seed and soil are brought together are the three greatest important factors in any infectious disease, whether naturally contracted or experimentally produced. In the study of the problem of human pulmonary tuberculosis all these factors are beyond control, whereas in the field of animal experimentation they can be at least partially regulated. So a thorough understanding of the pathology of pulmonary tuberculosis is not possible from uncontrolled and uncontrollable human material. But if the important pathological processes of pulmonary lesions in man, such as, localization, progression, cavitation, bronchogenic spreads and retrogression, can be duplicated in the experimental

animal then one should be able to understand more clearly its human pathology.

In this article the authors presented the type of lesions obtained in the rabbit which simulate the main pathological features of tuberculous lesions in the human lung. The authors used intravenously in rabbits three strains of tubercle bacilli of three grades of virulence—low, medium and high—the three variants of a single-strain B. C. G. and also investigated the effect of reinfection with bacilli of high virulence in animals vaccinated with both living bacilli of low virulence and killed bacilli of high virulence. The results obtained by them were as follows:—

(a) Bacilli of low virulence—10 to 50 mg.:—very rarely killed the animals; marked pulmonary disease developed; the majority survived for three years. The pathological process in majority resolved within a year and this occurred more rapidly in the anterior and ventral portions of lung than in the posterior and dorsal portions and where the lesions persisted for three years no evidence of cavitation or bronchogenic spreads was found.

(b) Bacilli of high virulence—1 mg.:—death occurred within two months. 0.01 mg.:—death ensued within six months. Lesions progressed evenly in all parts of lung. Suppurating and ulcerating lesions and bronchogenic spreads most common—no gross cavitation.

(c) Bacilli of medium virulence—1 mg.:—animals survived for six months. Lesions—of varying degrees, some with complete resolution in anterior part and gross cavitation in posterior portion. 0.01 mg.:—animals survived for two years. Lesions—complete resolution in anterior portion and gross cavitation and bronchogenic spread in posterior part.

(d) Reinfection in vaccinated animals—extensive pulmonary involvement within two weeks. Some lived for six months with marked resolution of lesions in anterior and ventral lung and gross cavitation with bronchogenic spreads in posterior and dorsal areas.

The difference of the nature of lesions between the anterior and posterior portions of lung led the authors to investigate the possibility of altering the localization of lesions by changing the posture of the animals. They were successful in shifting the main progressive tuberculous process from the caudal to the cephalic portion of the lung parenchyma with the change of posture from normal to upright position for ten hours daily, thus opening up a new avenue of approach toward the explanation of the rationale of apical or sub-apical tuberculosis in man.

From the above findings the authors made these comments that the natural inhalation route of infection is not of prime importance in localizing the progressing cavitating tuberculous lesions as all types of lesions have been obtained by the intravenous inoculation in animals; that the allergic condition of the tissue as a result of primary infection with the subsequent reinfection cannot determine the localization of cavitating tuberculous lesion as similar lesions (the so-called adult human type) have been obtained in animals from first infections with bacilli of every grade of virulence; and that the higher portions of the lung field appear to be less resistant to tuberculous infection than the lower portions as the most progressing cavitating lesions always occurred in these animals in the uppermost part of the lung, whether the animal is in the normal or upright position. The authors concluded that a certain balance between the resistance of the host and the virulence and dosage of parasite must be established either in the first or subsequent infection to obtain localizing cavitating lesions and the so-called adult type of human pulmonary tuberculosis is due in large part to the lodging of the tubercle bacilli in the less resistant upper units of the lung parenchyma.

The Intensity of Tuberculin Reaction and Frequency of Demonstrable Tuberculous Lesions

By C. W. WELLS

and

H. H. SMITH

(Abstracted from the *American Review of Tuberculosis*, Vol. XXXIV, September 1936, p. 425)

THE variation in the degree of reaction to the tuberculin test has long been observed. With the advent of intracutaneous tuberculin test, the extraneous factors which are operative with the cutaneous test being largely removed, sufficient interests have been aroused in this varying intensity of the reaction. Investigations have been conducted by various workers to interpret the meaning or importance of this variation in intensity and to correlate it with the degree of infection. The first study of this problem was made by Roemer and Joseph in the guinea-pig, using high dilutions of tuberculin, and they reported a definite correlation between the degree of infection and the intensity of tuberculin test. In recent years investigations were made to associate the more pronounced reactions to intracutaneous tuberculin test with active tuberculosis, on a quantitative basis, and to establish a critical threshold in the dilution of tuberculin which would more or less definitely exclude in the majority of negative reactors the possibility of active tuberculosis.

The present authors conducted a tuberculosis survey in Kingston, Jamaica, from 1931 to 1934 in which 4,906 individuals (a random sample of the population) were tuberculin tested and received chest x-ray examinations. They found that in the 0 to 9 years age group the per cent presenting lesions ranged from 0.5 per cent for negative reactors to 1 mg. to 14.1 per cent in two-, three- and four-plus reactors to 0.01 mg., in the 10 to 14 years age group, no lesion in negative reactors and 14.2 per cent of lesions in the above class of positive reactors and for all ages over 15 years, 5.5 per cent of lesions in negative reactors and 12.1 per cent in the positive reactors.

The average percentages showing lesions are 1.6 in negative reactors to 1 mg., 4.0 in positive reactors to 1 mg., 8.6 in one-plus positive reactors to 0.01 mg., and 12.4 in two-, three- and four-plus positive reactors to 0.01 mg. Thus an increase in the percentage of demonstrable pulmonary lesions, both active and latent, was found by them with an increase in the severity of the tuberculin reaction. The results are shown to be comparable to those of Opie and his associates (1926) for individuals in the school age groups. It was also specially mentioned that a negative reaction does not absolutely exclude active or far advanced tuberculosis as pointed out by Rich and McCordock. Opie and others found 17.3 per cent while the authors found 1.6 per cent of lesions in the group of negative reactors—two of the individuals of this group in the authors' series were suffering from far-advanced active disease.

S. R. G.

Contact as a Factor in the Transmission of Tuberculosis

By CHARLES SCHUMAN

(Abstracted from the *American Review of Tuberculosis*, Vol. XXXIV, July 1936, p. 85)

IN this study an attempt was made to determine the relative importance of different types of exposure in the dissemination of tuberculosis with a view to its control. Three thousand and fifty-seven patients of a tuberculosis clinic, of whom 1,802 were adults and 1,255 children (up to 16 years of age), were the subjects for this survey. According to the history and sputum examination report of the sources of contact the types of exposure were differentiated under five categories: (1) positive sputum, (2) negative sputum, (3) unknown

sputum, (4) deceased cases of tuberculosis, and (5) no known tuberculosis or non-tuberculous cases. The diagnosis of tuberculosis in children contacts was made by history and x-ray. No attempt was made to differentiate between so-called childhood tuberculosis and the adult type. The evidences of tuberculous infection in these children were determined by the intracutaneous Mantoux test, done in the usual manner, with 0.1 mg. OT. The degree of reaction to Mantoux test was also noted from the size of the weal and the swelling of the arm and interpreted as 1+, 2+, 3+ or 4+.

There was a relatively large number (730) of definite cases of tuberculosis among adult contacts as compared to the striking small number (47) in children. Of these 33.5 per cent in the case of adults were in contact with known tuberculosis patients, in contrast with 80.9 per cent in the case of children. According to the author this latter high incidence is apparent as, in the case of a child, the family circle comprises almost the entire extent of his contacts.

The incidence of tuberculous disease in adult contacts according to types of exposure was 23.9 per cent with 'positive sputum', 13.0 per cent with 'negative sputum', 17.3 per cent (which is almost an arithmetical mean between the previous two figures) with 'unknown sputum', 36.7 per cent with 'deceased cases of tuberculosis' and 68.0 per cent with 'non-tuberculous'. In the case of child contacts 7.5 per cent of those exposed to positive sputum, 0.5 per cent of negative sputum group, 4.6 per cent of unknown sputum group, 1.0 per cent of deceased tuberculous group and 5.5 of non-tuberculous group contracted the disease. Regarding Mantoux reactions 65.6 per cent were positive under positive sputum, 27.9 per cent under 'negative sputum', 60.0 per cent under unknown sputum, 70.9 per cent under deceased tuberculosis and 40.2 per cent under 'non-tuberculous group'. Regarding the intensity of reaction the 2+ Mantoux reading was the most common and the 4+ reading the least common in all the groups. The largest number (17) of children exposed to positive sputum developed a 4+ reaction.

Thus children exposed to positive-sputum cases show a high incidence to both tuberculous disease and tuberculous infection. The intensity of the Mantoux reaction depends largely on the time interval between the period of exposure to positive sputum and the date of the test; the more recent the exposure, the greater the reaction to tuberculin.

The author concluded that contact to positive sputum is the greatest single factor in the spread of the disease, that children exposed to positive sputum show an increased degree of sensitivity to tuberculin, that pulmonary tuberculosis is not very common in infant and children, and that the control of positive sputum is the most effective means of limiting the spread of the disease.

The Intra-dermal Tuberculin Test in Nurses

By PETER W. EDWARDS, M.B., B.Ch. (Edin.)

(Abstracted from the *Tubercle*, Vol. XVIII, December 1936, p. 101)

THIS study gives a record of a short series of intra-dermal tuberculin test on nurses.

Fifty-four were Mantoux-positive on joining the staff; of these one became tuberculous in six months.

Eleven were Mantoux-negative on joining the staff. Of these two left after the first test; three remained negative: one on third test after four months, one on third test after three months, one on second test after two months and all remained quite fit; six became positive: one on third test after three months, one on second test after eight months, two on second test after ten months (all these four were fit up to the time of report), one in the next month and the remaining one on third test after two months (these last two became tuberculous within two and three months, respectively).

The author also added that out of 43 female domestics so tested, 40 were Mantoux-positive at the beginning and all remained free from tuberculosis. Of the three negatives, one could not be followed up, one remained negative after the third test ten months later and the other was positive on second test a month later and all remained quite fit.

Of the male outdoor staff only six were tuberculin tested. Five were positive at the beginning and the other was negative and remained so on third test after four months. All these appeared fit at the time of report.

Results of the Sanocrysin Treatment of Tuberculosis

By F. I. TERRILL

(Abstracted from the *American Review of Tuberculosis*, Vol. XXXIV, July 1936, p. 156)

FORTY-ONE cases, the majority (30) of which were far advanced and the rest moderately advanced, showing no improvement under the usual care, were treated with the soluble gold-sodium-thiosulphate intravenously. The dose was 10 mg. to start with and was gradually increased to 250 mg. which was maintained for from five to eight injections before a rapid increase to 500 mg. was given. The repetition of the last dose depended upon the tolerance of the patient. The injections were given at weekly intervals unless there was some reason for a longer intermission. Weekly urine analyses were made during the course of treatment and for at least six weeks following its conclusion. Only a slight and transient albuminuria occurred in two cases necessitating only an increase in the time-intervals. After 18 months of treatment the results were quite conclusive as to the value of the drug in selected cases. Clinically improved—18, markedly improved—10, not improved—10, and adverse results—3. A gain in weight of over 5 lb. occurred in 16 cases, roentgenogram improvement in 15 cases, a diminished amount of sputum in 19 cases, and the sputum became negative for tubercle bacilli in 10 cases.

Conclusions: intravenous gold is of value in the treatment of tuberculosis and has a definite place in the armament of a phthisiotherapist. It is applicable in selected cases only and should not be substituted for collapse therapy, even for a trial. The early bad results of this treatment following its introduction by Mollgaard in 1928 are thought to be caused by the injection of too large a dose (the customary maximum dose then being 1 gm.).

The Use of B. C. G. Vaccine Against Tuberculosis in Children

By C. KERESZTURI

and

W. H. PARK

(Abstracted from the *American Review of Tuberculosis*, Vol. XXXIV, October 1936, p. 437)

THIS study was made under three heads:

(1) Is the B. C. G. vaccine harmless? The vaccine was proved to be harmless by the following observations:

(a) Four hundred to five hundred guinea-pigs, rabbits and monkeys were injected with large quantities of living organisms and only one developed a moderate tuberculosis which might have been due to an accidental laboratory infection.

(b) One hundred and seventy-five young infants were vaccinated with B. C. G. but not exposed to tuberculosis after vaccination. All did as well as the controls with the exception of one case who developed clinical tuberculosis but whose autopsy was refused and hence the diagnosis not settled.

(c) Five hundred and fifteen children were vaccinated with living B. C. G. organisms and exposed to a human tuberculous source. Four of them died of tuberculosis and the rest did well as the controls. From the organs of three out of the four dead cases, the human and not the bovine type of tubercle bacilli was recovered.

(d) In 27 out of 31 instances of cold abscesses occurring at the site of vaccination, B. C. G. bacilli were recovered from the aspirated pus. In none of the instances could the bacilli be shown to have increased in virulence by stay in the human body for periods of one to ten months.

(2) Is the B. C. G. culture effective in the prevention of tuberculosis? To gauge the immunizing effect of the B. C. G. vaccination the tuberculosis death rate among the comparable groups of B. C. G. vaccinated cases and the controls was studied. The children known from birth were vaccinated by mouth with B. C. G. vaccines within the first ten days of life and those that were not known from birth, had no evidence of tuberculosis and had negative initial Mantoux test, were parenterally vaccinated with B. C. G. vaccine (intracutaneously or subcutaneously). Both these groups were studied with their corresponding control groups for periods up to eight years. There were 300 to 400 cases in each group. The total number studied was 1,445. It was also noted whether these children were exposed to a case of tuberculosis with positive sputum or to one with negative sputum or not exposed at all to tuberculosis. Among the control children, known from birth, the tuberculosis death rate was found to be more than twice as high as among the orally-vaccinated ones, while among those not known from birth it was about four times as high as among the parenterally vaccinated babies. Regarding non-tuberculous mortality which was 5.2 per cent in the total group, it was lowest in the parenterally vaccinated children (2.8 per cent). In all the groups compared, the exposure to tuberculosis was remarkably similar, only one-third to half of all cases in each group were exposed to open tuberculosis; about one-third to closed tuberculosis, and less than one-third not exposed at all to tuberculosis. Therefore the tuberculosis death rate difference was not the result of unequal exposure, but a reliable one and, after statistical analysis, was shown to be of probable statistical significance. As the tuberculosis death rate rises in both sexes with age, this B. C. G. study should be continued until the child reaches maturity and the authors selected a portion of these children for follow-up.

(3) Should the B. C. G. vaccination be used as a health measure? The tuberculosis death rate among the authors' control cases, i.e., B. C. G. unvaccinated cases, was 2.7 per cent which was 45 times greater than the corresponding figure among children of the general population and the death rate of children of open tuberculous families (7.2 per cent) was 120 times more than the corresponding number of the general population. These differences are so enormous that, in the authors' opinion, it is worth while to use the B. C. G. vaccine to diminish the risk of death due to tuberculosis among children of tuberculous families. As the contrast between the death rates of the groups compared becomes smaller with the increase in age of the children, the B. C. G. vaccine should be given as early as possible. The authors also think that, if all children of tuberculous families could be found at birth and separated from tuberculous contact three months before and after vaccination until allergy to tuberculin appears, the B. C. G. could be made much more effective. Thus the authors concluded that the B. C. G. vaccine is harmless to animals and to human beings, the parenteral method of vaccination is more effective than the oral, and the use of the B. C. G. vaccine, being harmless and helpful in increasing the resistance to tuberculosis, should be urged as a public health measure for the prevention of tuberculosis in those not yet infected but who may be exposed to tuberculosis in their own families.

Tuberculosis in Hospital Nurses

By J. HEIMBECK, M.D.

(Abstracted from the *Tubercle*, Vol. XVIII, December 1936, p. 97)

THE following are the results of the investigations on the Ullevål nurses and on tuberculous diseases among them. The author employed the von Pirquet's test in the investigation. The working theory of the author was that tuberculous diseases in general manifest themselves at the time of primary infection, or immediately after it, i.e., whilst they are becoming allergic. At the beginning of the investigation there were some nurses who were von Pirquet-positive and who passed their primary infection without any disease, and others were negative to the von Pirquet's test. He found that after three years' service in the hospital all von Pirquet-negative nurses became von Pirquet-positive and some of whom passed their primary infection without any disease. He vaccinated some of the von Pirquet-negative group with B. C. G. vaccine and of this group, some were rendered von Pirquet-positive by vaccination and some remained negative after the vaccination. Afterwards some of the above negatives in connection with the vaccination passed their primary infection without any disease. The results were as follows:

(i) Morbidity among the nurses who passed the primary infection without any disease: 800 persons with 3,502 observation years 30 ill, i.e., morbidity of 8.5 per 1,000 observation years.

(ii) Morbidity among those who were primarily infected: 387 persons with 765 observation years and 118 ill, i.e., morbidity of 152.9 per 1,000 observation years.

(iii) Total morbidity among the B. C. G. vaccinated: 439 persons with 1,260 observation years and 33 ill, i.e., morbidity of 26.1 per 1,000 observation years.

(iv) Morbidity among those who became von Pirquet-positive in connection with B. C. G. vaccination: 287 persons with 910 observation years and eight ill, i.e., morbidity of 8.3 per 1,000 observation years.

Bilateral Pneumothorax and Pregnancy

By E. SCHILL, M.D.

(Abstracted from the *Tubercle*, Vol. XVII, September 1936, p. 551)

THE majority of people believe that pregnancy in tuberculous patients is harmful because extension of the disease is possible during pregnancy and because such extension occurs in childhood and afterwards. Pneumothorax offers possibilities of improvement of tuberculosis during the development of pregnancy. Case reports show that some even with extensive bilateral disease when treated with collapse therapy improve and bear well the efforts of labour, while others go down hill. So it is better to treat a patient with collapse therapy and watch her during the first three months of pregnancy. If, in spite of the treatment, the condition of the patient becomes worse the pregnancy should be terminated as interruption of pregnancy is possible any time within the first three months, though earlier the better, whereas interruption after three months has the same risk as in full-time birth. On the other hand, if the patient improves with the treatment of collapse therapy or if she presents herself after the third month, the pregnancy should be continued.

In pregnancy, with the increase of the uterus, the diaphragm is pushed up as in phrenicotomy, thereby diminishing the volume of the chest cavity. For this reason the disease generally improves during the second half of pregnancy and the same amount of collapse is obtained with smaller quantity of gas given at greater intervals. But after delivery the diaphragm suddenly descends as the uterus diminishes in size and a quiescent process flares up and smaller quantity of gas at greater

intervals becomes insufficient. So immediately after child birth refills should be commenced.

In unilateral treatment, during refills such quantity of gas should be given as will produce the maximum collapse. Gas given beyond this point will increase the pressure and not the collapse owing to the weakness of the mediastinum. In bilateral treatment each side is filled separately and there is no chance of pushing over the mediastinum or torsion of the great vessels. It is better to begin first on the side which shows more resorption. Owing to the greater strain on the heart digitalis is recommended if the pulse and respiration rates increase.

Observations on the Red-cell Sedimentation Test in Pulmonary Tuberculosis

By H. A. PATTERSON

(Abstracted from the *American Review of Tuberculosis*, Vol. XXXIV, July 1936, p. 164)

THE sedimentation reaction is a non-specific reaction of citrated blood and is generally regarded as a measure of pathological activity. The test cannot be used in diagnosis. To determine its relative value a study was made on 312 pulmonary tuberculosis cases. A total of 1,698 sedimentation tests was done. In performing the tests the 1 c.cm. technique as described by Cutler was employed. The sedimentation index and the sedimentation time were recorded and the results were graphically expressed to obtain sedimentation curves, generally divided into four groups: (a) horizontal line (normal), (b) diagonal line (mild activity), (c) diagonal curve (moderate activity), and (d) vertical curve (severe activity). The 312 cases reported consisted of 180 patients under treatment in hospital, 110 discharged cases, and 22 fatal cases. The cases were classified according to the National Association classification into three groups—incipient, moderately advanced and far advanced, and each of these into active, quiescent, apparently arrested and arrested according to pathological and clinical pictures.

The normal index, based on a study of 20 adult males, was 3.5 mm. The incipient cases gave an index of 3.9 mm.; the moderately-advanced cases 7.0 mm. and the far-advanced cases 14.1 mm. The active cases (795 tests) gave an index of 12.9 mm.; the quiescent cases (294 tests) 6.0 mm.; the apparently arrested cases (193 tests) 4.9 mm. and the arrested cases (316 tests) 3.2 mm.

The artificial pneumothorax cases in this series showed an improvement in the index in proportion to the degree of collapse obtained. The clinical improvement following pneumolysis operations (in seven instances) was also shown by the index. With a few exceptions the index coincided with the pathological involvement in most of the 312 cases. The test was found to be helpful in eliciting changes in some cases earlier than would be shown by temperature, pulse or respiration. Because of the value and simplicity of the test the patients should be advised to have frequent sedimentation tests done after leaving the hospital.

S. R. G.

The Diagnosis of Cavities in Pulmonary Tuberculosis by Means of the Tomograph

By J. B. McDOUGALL, M.D.

(Abstracted from the *Tubercle*, Vol. XVII, July 1936, p. 452)

FORMERLY, when most of the sanatoria and the dispensaries were not equipped with x-ray apparatus, it was very difficult for a medical officer to arrive at a

definite diagnosis of tuberculosis, and he had to depend mainly on physical signs. But, after the war, with the introduction of collapse therapy and the proper and accurate diagnosis the demand for the x-ray has increased, and now every properly-equipped unit must have x-ray facilities available. With the increase of x-ray plants and with the development of thoracic surgery, the standard of x-ray pictures has greatly improved. But the new method of tomography is a further advance on all previous x-ray techniques, specially in the diagnosis of cavities which may be obscured from direct vision in the usual antero-posterior x-ray pictures. In x-ray pictures we not only see the shadow of the lung tissue but that of ribs also which may obscure a lung lesion or may lead to distortion of the lesion. X-rays may fail to detect small cavities, especially when they are situated in the posterior aspect of the lungs, but the tomograph will help us to detect such cavities. The tomograph can take actual sections of the chest at any level but for ordinary purposes three sections are taken: (1) Ventral—about 7 cm. from the anterior chest wall, (2) medial—at the level of the hilum, and (3) dorsal—about 7 cm. from the posterior chest wall. In the tomograph the shadows of the ribs are almost eliminated, the sternum and the vertebral column are not shown as bony structures, though in the dorsal section the outer ends of the ribs and the outline of the vertebral column may appear. Such results are obtained only because the tube and the film holder move in a contrary direction during the time of exposure which is normally of one second. With this instrument we can reproduce only a plane of the chest at any level when the tube and the film describe an arc of about 45° during the exposure, but when the arc becomes less and less, for which the apparatus has additional adjustments, the sections reproduced become thicker and thicker, and, when the tube and the film are kept stationary, the entire thickness of the chest is reproduced. Lateral views are difficult to read with a tomograph for the appearances of a certain number of unknown shadows.

Tuberculin P. P. D. in the Treatment of Tuberculosis

By B. C. THOMPSON, M.A., M.D. (Camb.)

(Abstracted from the *Tubercle*, Vol. XVIII, October 1936, p. 27)

P. P. D. in tablet form containing 0.05 mg. of active substance was used. It was dissolved in 1 c.c. of diluting solution supplied by the manufacturers (Messrs. Parke, Davis and Co.) and then made up to 10 c.cm. by sterile water in a sterile rubber-capped bottle. When needed the required amount could then be withdrawn from this bottle by a needle and syringe.

Injections were given subcutaneously every week into alternate arms. If the reaction from the previous injection persisted, the interval was prolonged. In non-pulmonary cases the initial dose was 0.02 c.cm. (0.0001 mg. P. P. D.). The second dose was 0.05 c.cm. and thereafter the dose was doubled weekly until a local reaction was produced. After this the dose was increased by one-quarter to the limit of tolerance. In this series the treatment was successfully completed in periods varying from two to twenty-six weeks.

This treatment was given to 59 patients. This included the following:—cervical gland tuberculosis—54; pulmonary tuberculosis—2; tuberculosis of the hip—1; renal tuberculosis—1; phlyctenular keratoconjunctivitis—5 (four of them had cervical gland tuberculosis).

There was improvement in 32 amongst the group of 54 cervical gland tuberculosis. Considerable reduction in the size of the glands occurred in 13, great reduction in ten and in nine glands are almost impalpable. It

was found that when palpable fluctuation was obtained in the glands, surgical treatment was required in addition to medical treatment.

This method of treatment was not successful in other types of the disease included in this series.

The results obtained by P. P. D. treatment in this series were found to be inferior to the results obtained by the same author by Beraneck's tuberculin treatment in a series of 42 cases of cervical gland tuberculosis.

It was suggested that P. P. D. is relatively deficient in that tuberculin principle which produces focal reaction and the beneficial results obtained are due mainly to the increase of general immunity level. The author therefore suggested that P. P. D. used for intradermal test would be safer than old tuberculin because there would be less possibility of lighting up latent tuberculous foci.

Reviews

ARTIFICIAL PNEUMOTHORAX: EXPERIENCE OF THE LONDON COUNTY COUNCIL.—By F. J. Bentley. Medical Research Council, Special Report Series No. 215, 1936. Published by His Majesty's Stationery Office, London. Pp. 94. Illustrated. Price, 1s. 6d.

In part I of the book the author gives an extensive digest of literature on artificial pneumothorax of almost all the countries, and pointed out the shortcomings in these articles which were unfortunately too frequent. He concluded that 'seven deadly sins which all investigators in this field must avoid are as follows:—

1. *Paucity*.—To draw conclusions from too small a number of cases.

2. *Selection*.—To write up only certain of one's cases.

3. *Precipitancy*.—To report on cases before a sufficient period has elapsed.

4. *False control*.—To evaluate results by comparison with the fate of patients having extensive pleural adhesions.

5. *Equivocation*.—To employ equivocal definitions as to degree of collapse.

6. *Failure to trace*.—To lose sight of a high proportion of patients.

7. *Lack of detail*.—To fail adequately to describe the extent of disease'.

Amongst these sins he specially stressed the importance of taking those cases where pneumothorax was not possible, due to adhesions, as the control group. Cases with pleural adhesions fare worse than those with free pleural space even when there is no question of pneumothorax therapy. He, therefore, emphatically says that such controls would not be accepted in assessing the result of pneumothorax therapy.

He attempted to clarify the position of pneumothorax therapy by a study of the London experience. In about 10 per cent of all cases of pulmonary tuberculosis pneumothorax was done of which less than one-quarter consisted of strictly unilateral and complete collapse cases. Six hundred and seventy-seven new cases of pneumothorax were followed up over a period of three to thirteen years. Five hundred and eleven of these were investigated in considerable detail. His control group consisted of 3,329 cases. These were treated by the conservative method only and were drawn from identical sociological and environmental sections of the population. He did not claim this group to be a perfect statistical control, the attainment of which, he considers, is not possible, but this provides a useful base line from which to evaluate, in broad outline, the results of pneumothorax treatment.

The pneumothorax group consisted of—

(A) Cases in which tubercle bacilli have never been demonstrated in the sputum, pleural fluid, faces, etc.—7.2 per cent.

(B) Sputum positive in tubercle bacilli.

(B1) Cases with slight constitutional disturbance if any, and slight extension—3 per cent.

(B3) Cases with profound constitutional disturbance—14.5 per cent.

(B2) Intermediate group between (B1) and (B3)—75.3 per cent.

The average period of the duration of pneumothorax treatment in all cases was 18.8 months and in the complete cases the average period was nearly three years.

Of these 677 cases, 411 were observed over a minimum period of five years and the rest over a minimum period of three years. The control group of 3,329 were followed up for five years.

RESULT OF TREATMENT ACCORDING TO SEX AND AGE

Three-year survivals—677 cases

Males—Results of treatment seem good, i.e., statistically significant at ages 15 to 34, 40 to 44 and all ages.

Females—Results significant at ages 15 to 19, 25 to 39 and all ages.

Three-year survivals—411 cases

Males—Results significant at ages 15 to 24 and all ages.

Females—Results significant at ages 15 to 19, 25 to 34 and all ages.

Five-year survival—411 cases

Males—Results significant at ages 20 to 27, 40 to 44 and all ages.

Females—Results significant at ages 15 to 34 and all ages.

A striking fact evolved was that the age group of 20 to 25 yielded good results in males and poorest results in females. In both sexes the age group of 25 to 30 produced favourable results.

Result of the treatment in the 677 new cases showed that at the end of three years there was 19.1 per cent gain in lives as compared to the conservative group. In the smaller group of 411 cases—the gain in lives after three years was 18 per cent and at the end of five years 19.8 per cent.

The difference of result between complete collapse and incomplete collapse cases was very striking. In the whole series 60 per cent belong to the incomplete collapse group and 40 per cent to the complete collapse group. In this incomplete collapse group only 50 per cent survived a period of three years while in the complete collapse group 65.9 per cent were alive after three years and when the disease was strictly unilateral the percentage of survivals rose to 77.4.

The author lays special stress on the result in 'complete' unilateral cases. Even with complete collapse the presence of only slight contralateral disease materially reduces the chance of survival. Strictly unilateral cases even with incomplete collapse fared better than complete collapse cases with but 'slight' contralateral involvement.

He stresses the point that we should concentrate on collapse and not on pneumothorax therapy only; and no effort must be spared to obtain optimum collapse. Complete collapse more often renders the sputum negative than incomplete collapse. In complete collapse group 65 per cent were sputum negative and in the incomplete group it was less than 50 per cent. In the sputum-negative group 90 per cent of the subjects were alive after three years whereas in the sputum-positive group it was approximately 75 per cent.

Pneumothorax in suitable cases also made the lesions quiescent quicker. In this group the disease became quiescent at the end of three years in 65 per cent of cases, whereas in the conservative group it was 38 per cent. Working capacity was also increased in the pneumothorax group.

The author stresses the importance of after-care and states that it should be strictly followed both in pneumothorax cases and also those cases who quiesce without pneumothorax.

In conclusion, he states that in these 10 per cent of all cases the improvement was 20 per cent, so the improvement by this method of treatment in all cases would be about 4 per cent which will not materially alter the gross statistical results of all cases of tuberculosis. But this therapy will continue to be of vital importance to selected individual sufferers.

P. K. S.

TRACHOMA.—By A. F. MacCallan, C.B.E., M.D., F.R.C.S. 1936. Butterworth and Company (Publishers), Limited, London. Pp. xvii plus 225. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 14

THIS monograph has been written to take the place of the author's former *Trachoma and its Complications in Egypt* (Cambridge University Press, 1913), and embodies the Hunterian Lecture at the Royal College of Surgeons of England 1936 on the surgery and pathology of trachomatous conjunctivitis.

So much work has been done on trachoma during the last ten years that an up-to-date book on the subject was badly needed and surely no one was more worthy to undertake this task than Mr. MacCallan with his vast experience of this widespread disease. The author has discussed his subject in great detail in nine chapters. These consist of an introduction to the study of trachoma, the clinical manifestations, the sequelæ, the complications, the differential diagnosis, the treatment, the pathological anatomy, the epidemiology and, finally, the history. There are also two indices—the author and the subject.

In a country like India where trachoma is so prevalent, the chapter on treatment will be of special interest as many of the sequelæ one sees are due to incorrect medical treatment and mutilating operations. How often does one come across cases of trichiasis and entropion treated by the removal of a piece of skin from the lid which should never be done. One must question the accuracy of the figures in the incidence of trachoma in India although they are taken from the Annual Report of the Public Health Commissioner with the Government of India 1931 and the War Office Report 1931. It would be of interest to know who was responsible for the investigations. In Bengal where there is a population of 50 millions trachoma is uncommon, except in those who have recently migrated from northern or central India.

It is also interesting to know that the ætiology of trachoma is still incomplete, as the *Bacterium granulosis* of Noguchi has not been proved to be the causative organism. The clinical diagnosis in the absence of elaborate apparatus may be impossible and no aids are to be obtained by microscopical or chemical tests.

The book is a most excellent one and can be regarded as a classic. It is written in a clear, simple manner and the illustrations and reproductions of paintings are numerous and most excellent.

India in general must owe a great debt of gratitude to the author for reproducing an up-to-date book on this important disease which is responsible for so much suffering and blindness. We strongly recommend it to all ophthalmic surgeons in India and to medical officers who are interested in the subject of trachoma.

E. O'G. K.

FAVOURITE PRESCRIPTIONS.—Edited by Sir H. Rolleston, Bt., G.C.V.O., K.C.B., M.D., F.R.C.P., and A. A. Moncrieff, M.D., F.R.C.P. 1936. Published on behalf of the 'Practitioner' by Eyre and Spottiswoode (Publishers), Limited, London. Pp. 227. Price, 10s. 6d.

We have referred elsewhere in this number to that excellent journal, *The Practitioner*.

A very useful series of articles that they published during the last year or so was entitled *Favourite Prescriptions*; these have now been issued in book form. Each contribution was a short discussion on the pharmacopoeia of one of the leading London hospitals, either general or special.

The first chapter is rightly devoted to the pharmacopoeia of St. Bartholomew's Hospital, London's old hospital, founded in the year 1133. Its first pharmacopoeia was however not published until more than 600 years later, 1743. No prescriptions appear to have survived the two hundred years since this date, but many prescriptions have undergone few or unimportant changes during the last fifty years.

We claim to be followers of a progressive science but it may be said to our credit that when we see that a thing is good we are very ready to leave well alone.

An interesting contrast is the chapter on the favourite prescriptions of the Tropical Diseases Hospital. There quinine is almost the only drug that is not a parvenu. It must shake its family pride to have to associate with such upstarts as atabrin, neostibosan, carbon tetrachloride, yatren and tryparsamide.

This is a book which should prove to be a 'best seller' as it will appeal to many of us on account of the memories it revives, very much to our advantage if we have strayed away from the habit of writing simple and cheap prescriptions, and to others who were—in our opinion—less fortunate and received their medical training elsewhere by placing at their disposal time-honoured and cheap prescriptions suitable for almost any occasion that may arise in their daily practice.

L. E. N.

EXOPHTHALMIC GOITER AND ITS MEDICAL TREATMENT.—By I. Bram, M.D. Second Edition. 1936. The C. V. Mosby Company, St. Louis. Pp. 456, with 79 illustrations. Price, \$6.00.

THIS monograph on the subject of Grave's disease is based on the experiences of the author who has been treating this malady by medical means for over two decades and on his studies on this subject. The author has discussed the various theories as to the causation of the disease and has adopted the hypothesis that the disease is a 'generalized dysfunction of the vegetative nervous system and the entire chain of endocrine organs—a neuro-endocrine dysfunction'. The patient is believed to have an inherited or rarely an acquired neuro-endocrinopathy, serving as the predisposing factor, and it requires but the torch of an exciting cause, usually an emotional strain, a psychic trauma or, rarely, an intoxicant, to light up the symptoms. To support his theory as to the value of the exciting causes, he has cited a large number of case histories.

To the protean symptomatology of the disease no less than six chapters have been devoted and a fairly exhaustive account of the symptoms and complications has been given. A full description of the various eye signs associated with exophthalmos has been given. It is time that those signs that 'do not add materially to the ease and certainty of diagnosis' and that have become a tradition in medicine, should receive less important attention. Description and enumeration under symptomatology of all sorts of symptoms, viz. neuritis, tetany, scurvy, osteoporosis, etc., observed occasionally in Grave's disease appear to be of doubtful value.

Diagnosis and differential diagnosis have been dealt with thoroughly. The author has tried to differentiate between thyrotoxicosis and Grave's disease by considering no less than twenty points of difference. The entity

of most of the differentiating points is, to say the least, doubtful and the difference between the symptoms of thyrotoxicosis and Grave's disease is really very little.

The author has discussed a large number of tests and has found the estimation of basal metabolic rate and the quinine test to be useful. No mention is made of the methods of estimation of the basal metabolic rate or of the simple formulae, *e.g.*, Reid's, employed for the purpose.

The author believes the treatment to be entirely non-surgical by adoption of hygienic, psychotherapeutic and medicinal measures. He regards surgery and destructive radiation as palliative measures only. To support his views he has brought forward the successful results of a large number of cases treated medically.

If his methods are followed with similar success in other parts of the world by other authorities on the subject, the standard textbook teaching that medical treatment is but palliative and that curative treatment is either by surgery or destructive radiation of the thyroid, and the dictum that the 'indication for operation is the diagnosis of hyperthyroidism' will have to be revised.

R. C.

THE OPERATIONS OF SURGERY.—By R. P. Rowlands, M.S. (Lond.), F.R.C.S. (Eng.), and P. Turner, B.Sc., M.S. (Lond.), F.R.C.S. (Eng.). Eighth Edition. 1936. Volume I. (The Upper Extremity—The Head and Neck, The Thorax, The Lower Extremity, The Vertebral Column.) J. and A. Churchill, Limited, London. Pp. x plus 1045, with 435 illustrations (38 in colour). Price, 36s.

For nearly half a century Jacobson's 'Operations of Surgery' has been in the library of almost every practising surgeon. This first volume of the eighth edition has fully maintained the high standard of its predecessors, but one cannot help regretting that though the general arrangement and much of the text remain as written by the late Mr. W. H. A. Jacobson, his name has now disappeared from the title and has been given but brief reference in the preface.

The present editors have had the assistance of several distinguished members of the staff of Guy's Hospital in rewriting specialized sections of this edition. To one familiar with previous editions, the new sections are readily picked out. Without exception they are excellent; one would be surprised to find otherwise in this work. They are also well balanced in length and manner of presentation, features usually lacking in works of multiple authorship. Continuity of style is fair, but in this respect perfection is impossible under the circumstances.

Textbooks on operative surgery are usually encumbered by the description of a number of operations which are often set as tests of surgical anatomy at operative surgery examinations, though seldom performed on the living subject. The post-graduate finds these operations fully described for his benefit in several books on surgical anatomy. They should have no place in a work of an essentially practical nature. In this volume several of these have been omitted. There is, for example, no mention of the Chopart and Lisfranc amputations. The editors are to be congratulated on having the courage to leave them out, and it is to be hoped they will carry the principle further in future editions.

J. C. D.

SYNOPSIS OF ANO-RECTAL DISEASES.—By L. J. Hirschman, M.D., F.A.C.S. 1937. The C. V. Mosby Company, St. Louis. Pp. 288, with 174 text illustrations and 6 coloured plates. Price, \$3.50.

We have nothing but praise for Dr. Louis J. Hirschman's little book, *Synopsis of Ano-Rectal Diseases*, for it clearly describes the outlines of diagnosis and treatment of all the common affections of

the anus and rectum in a manner which will be of great assistance to the general practitioner.

The first third of the volume is entirely devoted to methods of examination, enumeration of equipment, etc., and, though this may seem to be excessive in a work of this size, the description is so excellent and so full of sound common sense that the amount of space taken up could not be lessened without detracting from the usefulness of the book.

In the section on hæmorrhoids the author, like that great English proctologist, Ernest Miles, exhorts the general practitioner to take a greater interest in this disease, and never to treat a case of rectal bleeding as merely one of piles, without a very full examination of the anus and rectum. Plate I which illustrates a carcinoma of the rectum complicating prolapsing hæmorrhoids is an example of the great importance of examining all cases of piles in the fullest manner.

Anal papillitis, rectal prolapse, and the removal of foreign bodies from the anal canal and rectum are fully dealt with. The book is well printed and the illustrations are good.

H. E. M.

WEIGHT REDUCTION DIET AND DISHES.—By E. E. Claxton, M.B., B.S. (Lond.), D.T.M. & H. With Recipes by Lucy Burdekin. 1937. William Heinemann (Medical Books) Limited, London. Pp. x plus 199. Price, 8s. 6d.

A STUDY of the history of man has shown him at all times concerned with his self-preservation and protection in a world which was full of unforeseen and often unpleasant contingencies. Abstinence from food or drink in the interests of a propitiating diety and later on asceticism in the hope of salvation in the next world were often the motives. The present century has however seen a waning absorption in the future and a greater attention of man on himself, his fellows and the present.

The cult of weight reduction by diet and exercise is probably designed to attain better health, retain youth, and the approval of others, in which notably the desire for sex appeal plays a large part. The methods employed, namely diet and exercise, are probably the modern form of the abstinence practised by primitive man along with the more positive athleticism of the Greeks. Whatever Freud may say about the real nature of inhibition taboo, who can deny that the present cult is more or less rational in its object and in its methods?

The author has written quite a sensible book on weight reduction, not quite but almost, without tears. The main principle simply is that the calorie intake should be suitably adjusted so as to be slightly below the requirements but not such as to cause a great loss of protein or an acidosis. No drugs are recommended, attention to exercise and food are the bulwarks of the scheme. A number of useful recipes is given—a biscuit sweetened with saccharine and containing bran, gum and mineral oil as a dough mixture is the most formidable. The scheme is graduated and success depends largely on self-discipline while carrying it out.

H. E. C. W.

A TEXTBOOK OF SURGERY.—By American Authors. Edited by F. Christopher, B.S., M.D., F.A.C.S. 1936. W. B. Saunders Company, Limited, Philadelphia and London. Pp. xix plus 1608, with 729 illustrations. Price, 42s.

A WELL-BOUND, well-printed and well-illustrated book following the classical arrangement of the English surgical textbooks. Indeed, the similarity of the arrangement to those of Rose and Carless is rather striking.

The subject has been divided into many small sections, each signed by its author. One hundred and eighty-nine authors have taken part in the compilation, the list of them occupying ten pages. Many names of international repute occur in this list and no pains have been spared to make the contributions as complete as was consistent with space available.

This method of compilation has resulted in an authoritative work of reference in a reasonable compass. To the practitioner it can be recommended for this purpose. The student will also find it useful for reference, but for systematic study will probably prefer a broth prepared by fewer cooks.

J. C. D.

CYSTOSCOPY AND UROGRAPHY.—By J. B. Macalpine, F.R.C.S. (Eng.). Second Edition. Revised and Enlarged. 1936. John Wright and Sons, Limited, Bristol. Pp. xv plus 478, with 297 illustrations in the text and 14 coloured plates. Price, 30s.

It is some ten years since the first edition of this book appeared, prior to which the surgeon desiring a volume dealing solely with cystoscopy had been forced to resort to foreign publications. It filled a need at the time, and it can be safely predicted that this up-to-date second edition will be equally popular.

The text of the present edition has been almost completely rewritten and is nearly half as large again as the original. This is partly due to the addition of urography to its scope—with consequent addition to the title—but is also due to fuller text and greater number of illustrations, the latter being practically double the number in the first edition.

The practical use of the instrument is described fully but not tediously. The pathology is well illustrated, the coloured plates being particularly true to life. The controversial subject of endoscopic prostatic resection is discussed in a fair and interesting manner. Sections dealing with renal function tests, pelvic resorption and congenital anomalies have been included.

Though all who use the cystoscope can profit from this book, it will be of particular value to those whose opportunities for genito-urinary work do not occur with sufficient frequency to keep them skilled in the use of endoscopic instruments. The trifling mistakes which so frequently shipwreck the efforts of the occasional operator may be avoided by a study of the explicit practical data given.

J. C. D.

SICK CHILDREN: DIAGNOSIS AND TREATMENT.—By Donald Paterson, B.A. (Manitoba), M.D. (Edin.), F.R.C.P. (Lond.). Second Edition. 1937. Cassell and Company, Limited, London. Pp. 600, with 15 half-tone plates and 76 figures in the text. Price, 12s. 6d.

This is a practical handbook of children's diseases designed for the student and the practitioner. Stress is laid on symptoms, diagnosis and treatment, but aetiology and pathology are by no means neglected. There are numerous illustrations. The style is particularly concise and clear and a large amount of information is given in a very compact volume. Descriptions of less common conditions are printed in smaller type and references to other works are numerous and are printed as footnotes instead of at the end of chapters. These points will commend the book to students working for examinations. A table of normal data relating to children is printed on the inside of the cover. There are two appendices, one giving quantities of drugs for children at different ages, and the other giving copies of recent examination papers in pediatrics and nursing of sick children.

The methods of feeding the healthy and sick infant are described in detail and disorders of nutrition are treated more fully than other diseases of children. The clear directions regarding diet in treatment are perhaps the most valuable feature of the book. This edition includes a description of the later work on the nutritional anæmias of infancy.

The book deals with facts rather than theories and provides an excellent introduction to the study and practice of pediatrics.

M. N.

SAFE CHILDBIRTH—THE THREE ESSENTIALS—
1. ROUND BRIM. 2. FLEXIBLE JOINTS.
3. NATURAL POSTURE.—By K. O. Vaughan, M.B. (London). 1937. Baillière, Tindall and Cox, London. Pp. ix plus 154, with 49 illustrations. Price, 7s. 6d.

This stimulating and original book dealing with the problem of childbirth is written by one with a long experience of midwifery in India. Her investigations followed her personal observation of the contrast afforded by the easy and safe labours of women living under natural and healthy conditions and the prolonged and often dangerous labours of *purdah* women. The book will therefore be of a particular interest to men and women practising in this country.

The object of the book is, the author says, a practical one, namely, 'to simplify our attendance on childbirth while making it a safer and easier process for both mother and child'. Dr. Vaughan has made a survey of customs during childbirth and the ways of delivery as practised in many parts of the world and at different periods of history. Her conclusions are important to a generation faced in the West with a more or less stationary maternal mortality and in the East with rapidly-spreading artificial conditions of living.

The author is convinced that the three essentials for easy and safe delivery are the round pelvic brim, flexible pelvic joints and the natural posture during childbirth. She presents very strong arguments in support of this theory and makes recommendations, some of which she has had the opportunity of testing, as to how they may be achieved. All who practise midwifery in this country will find much in their own experience to support what she says and the book will doubtless provoke considerable discussion and thought.

At a time when the process of labour is tending to become more artificial this book comes as a timely warning, and it may quite possibly result in a de-civilizing movement, regarding the preparation for and conduct of childbirth, which will greatly benefit the race.

M. N.

DENTAL SURGERY FOR MEDICAL PRACTITIONERS.—By B. A. Kopkin, L.D.S. (R.C.S.), Eng., with a foreword by Sir Norman G. Bennett, M.A., M.B., B.Ch. (Camp.), L.D.S. (Eng.). Henry Kimpton, London. Pp. x plus 109. Illustrated. Price, 5s.

This small book aims at establishing a liaison between the medical and dental professions in regard to cases which are referable to both the medical man and the dentist.

The title is slightly misleading as the book does not deal with the dental work which might fall within the scope of the general practitioner, but is more a warning to the doctor to avoid pitfalls in dealing with purely dental matters.

The book opens by postulating that mistaken diagnosis by the doctor may lead to recrimination after a visit to the dentist who has to revise the original diagnosis. Reading the book dispassionately, the doctor seems to occupy one of the Biblical pens, whether amongst the sheep or the goats is not too clear.

Most of the book is scrappy and contains little of abiding interest to the medical man.

Chapter II deals with the administration of nitrous oxide, and the anaesthetist is delegated to perform other duties than those purely concerned with anaesthesia. This is surely not quite the usual routine in operative procedure.

Chapter III is devoted to dental caries in which the doctor is advised to refer the patient to the dentist *before the tooth pains*. It is scarcely to be expected that the patient will consult a doctor before he finds something to complain about.

Chapter IV deals with pulpitis and periodontitis and the differentiation of gingivitis and pyorrhœa alveolaris is not very clear.

Chapter VI is two pages long and is devoted to toothache.

Chapter VII is probably the best in the book and deals with local anaesthesia, the illustrations being clear. The only anaesthetics mentioned are novocaine and cocaine.

Emergency treatment is discussed in chapter VIII and contains relevant matter relating to the extraction of teeth.

In chapter IX, dental treatment during pregnancy is touched on, and a diet full of calcium salts and vitamins is recommended. This part might have been extended and more subject matter included in relation to both calcium and the vitamins.

Chapter XIII deals with oral sepsis and general diseases. Here, in relation to general diseases, mention might have been made of diabetes mellitus, in which it is a common occurrence to find marked reduction of blood sugar following removal of a septic focus in the mouth.

This first chapter on 'some dental operations' will not tempt the medical man to venture into the realms of dentistry.

Although this little book is rather scrappy and incomplete, it might interest the busy practitioner, as the whole book can be read in a couple of hours.

This attempt to co-opt the two professions is laudable and the book might be of use to the newly-fledged medico, whose dental training is usually chimerical.

The skeletal framework of the book is complete, but a little flesh on the dry bones would lead to better action.

D. M.

RASA-JALA-NIDHI OR OCEAN OF INDIAN CHEMISTRY AND ALCHEMY.—By Kaviraj Bhudeb Mookerjee, M.A., Rasacharya. Published by the author from 20, Grey Street, Calcutta. Volume I, 1926; Volume II, 1927; Volume III, 1929; Volume IV, 1936. Price of each volume, Rs. 6

THESE four volumes form part of a series of ten volumes to be published on this subject of Indian chemistry and alchemy. In all these volumes the original Sanskrit text is first quoted and this is followed by an English translation. Volume I deals mainly with mercury, its attributes, purification, different operations with the metal, different preparations of mercury and their uses, as well as the description of some of the apparatus used. Some processes for the transformation of base metals into silver and gold are also described.

Volume II deals with inorganic compounds like mica, pyrites, saltpetre, salts of copper and iron, calamine, sulphur, sulphides of arsenic, antimony and mercury and metals like gold, silver and copper. The therapeutic uses of all the preparations are mentioned under each head. Volume III deals with the preparations and uses of metals like iron, zinc, tin and lead, alloys like brass and bell-metal, gems like diamond, emerald, ruby, pearl, sapphire, quartz, coral, amethyst, etc., alkalies, inorganic salts, inorganic and organic poisons and semi-poisons, and finally about some alcoholic liquors.

Volume IV starts with diet, dress, bath, etc., and passes on to different diseases and their treatment. Different kinds of fever, fever with diarrhoea, chronic diarrhoea, cholera, piles and diseases affecting the abdomen are all discussed and their treatment suggested. The methods of preparation of the medicines used are given in some detail and in some cases the necessary diet is also suggested. These medicines, which are mostly inorganic in nature, are taken with different adjuncts as is the custom in indigenous systems.

In compiling these volumes, the author has taken a lot of pains to collect much useful information in a form convenient for a wider section of the public both in India and abroad and he has thus earned the gratitude of all by this monumental work.

S. G.

A SYNOPSIS OF THE BRITISH PHARMACOPŒIA, 1932, AND OF THE POISON LAWS OF GREAT BRITAIN, NORTHERN IRELAND AND THE IRISH FREE STATE INCLUDING THE 1936 POISONS LIST AND RULES.—By H. W. Gadd. Thirteenth Edition. 1936. (With a Synopsis of the Addendum, 1936, to the British Pharmacopœia, 1932.) Baillière, Tindall and Cox, London. Pp. 200. Price, 3s.

THIS is the fourth appearance of this valuable little book since the publication of the 1932 British Pharmacopœia. In the present edition a synopsis of the Addendum of the British Pharmacopœia of 1936 is included.

The book contains all essential details of the composition, strength and dosage of all pharmacopœial drugs arranged in tabular form for quick reference, and other valuable tabulated information on weights and measures, the preparation of alcoholic solutions, etc.

It is a small volume that will easily go into the waistcoat pocket, and will be found invaluable for ready reference by both pharmacists and doctors.

TUBERCULOSIS, CANCER AND ZINC: AN HYPOTHESIS.—By D. B. Cruickshank, L.R.C.P. & S., L.D.S. (Edin.), D.P.H. (Camb.). 1936. Medical Publications Limited, London (25, Soho Square, W.1). Pp. xv plus 75. Illustrated. Price, 7s. 6d.

THE more widespread a disease, the greater the number of angles from which it can be envisaged. Tuberculosis and cancer, as diseases confined neither to man nor to specific areas of the globe, can certainly claim pre-eminence in this respect. The thesis of the author is that the relative incidence of these two maladies is inversely proportional, i.e., where one is high the other is low. He claims to show that in areas where the strata is rich in zinc or among zinc workers the incidence of tuberculosis is low, while that of cancer is high. Cancerous tissue appears also to have a relatively high content of zinc. The book is well written and should be read by those interested in the subject.

H. E. C. W.

Abstracts from Reports

ANNUAL REPORT OF THE UNION MISSION TUBERCULOSIS SANATORIUM, AROGYA-VARAM, NEAR MADANAPALLE (SOUTH INDIA), 1935-36

THE report gives a short history of the origin of the sanatorium, its situation, climatic conditions, accommodation and other activities.

During the year 642 patients were treated, 421 were admitted and 422 were discharged. The group of 'merchants' contributed to the highest number (65),

the 'students' next (58). In the age group the highest number was in men between 21 to 30 years and in women 21 to 25 years.

Of the 422 cases discharged, 371 were suffering from active pulmonary tuberculosis. Of these, 51 were not included in the assessment for insufficient stay. The remaining 320 cases dealt with showed 14.4 per cent in stage I, 13.4 per cent in stage II, and 72.2 per cent in stage III. Amongst all these 56 were 'arrested', 110 'much improved' and 61 'improved' by the treatment,

that is 'positive' results were obtained in 70.9 per cent. In the stage I cases 98.0 per cent, in stage II cases 90.7 per cent and in stage III cases 61.5 per cent showed positive results. In these 320 cases sputum was found to be positive in 73.1 per cent. All those in stage I could be made free from the bacilli. The sputa of 56.5 per cent of those in stage II and 29.9 per cent of those in stage III could be made negative to the bacilli.

In the pneumothorax group (94) 'positive' results were obtained in 54.3 per cent. The author is very much impressed by its effect even in stage III cases. In this group in successful cases 50 per cent were much improved whereas in unsuccessful cases due to adhesions only 26.1 per cent were much improved.

The author has found encouraging results in intestinal tuberculosis cases by ultra-violet and vitamin therapies.

The most illuminating part of this report is the result of the investigation of after-histories of his cases. He clearly showed the advancement in the treatment of tuberculosis by modern methods. Amongst those treated during the years of 1915 to 1920, only 23.1 per cent were discharged as 'clinically well' and 35.5 per cent were alive and well after five years, whereas those treated during the years of 1926 to 1930, 34.3 per cent were discharged as 'clinically well' and 64.6 per cent were alive and well after five years. The group of 1921 to 1925 produced intermediate results. The groups of 'arrested' and 'much improved' were termed as 'clinically well', because the author found from after-histories of his cases that both those groups did equally well after their discharge from the sanatorium.

P. K. S.

THE RAMAKRISHNA MISSION FREE TUBERCULOSIS CLINIC, DARYAGUNJ, DELHI. REPORT FOR THE PERIOD OCTOBER 1933 TO DECEMBER 1935

History.—The institution was started in a small rented house at Pahargunj in October 1933. Shortly afterwards it was noticed that most of the patients were coming from the city proper. The clinic was, therefore, moved to a larger house near Jama Masjid in August 1934. This place was also found unsuitable and in September 1935 the management transferred the clinic to the present building known as 'Hanging Bridge', close to Daryagunj Post Office. It is a spacious, well-ventilated and well-lighted building very suitable for an institution of this nature.

Objects.—Before the introduction of the new scientific methods, such as collapse therapy, sanatoria were considered to be the only places where this disease could be treated effectively, but medical opinion has changed considerably in recent years. Even comparatively advanced cases can now be treated successfully in an outdoor clinic. The object of this small institution is to offer the advantages of the most modern forms of treatment to poor consumptive patients.

Necessity of a tuberculosis clinic in Delhi.—Once a civil surgeon of Delhi stated at a meeting of his colleagues that there was hardly a family in the city, which could claim to be altogether free from this disease in an active form. We have reason to think that he was not far from the truth. Under the circumstances it is impossible for a hospital with 70 or 100 beds to cope with the situation. We believe that outdoor clinics serve several purposes. Firstly, they treat those patients who do not obtain admission in the hospital. Secondly, the treatment of the patients discharged from the hospital can be continued in a clinic. Besides these two classes of patients, there is another class who will not go into a hospital. They also can have treatment in the clinic. Further, an outdoor clinic is the most suitable place for carrying out preventive work, which is the most important thing in fighting the disease.

Equipment.—The clinic is equipped with the instruments and apparatus to do artificial pneumothorax and phrenicectomy operations. Several such operations have already been performed in this clinic.

Management.—The institution is managed by a working committee appointed by the local committee of the Delhi Ramakrishna Mission.

Maintenance.—In its earlier days, the clinic was maintained by monthly subscriptions and small donations from the general public. Subsequently, a grant-in-aid of Rs. 1,050 from the King George Thanksgiving (Anti-Tuberculosis) Fund and lump sum donations, such as Rs. 2,000 from the Maharaja of Vizianagram, Rs. 500 from Seth G. D. Birla, and Rs. 500 and Rs. 300 from two anonymous donors, have so far enabled this useful institution to carry on the work. Unfortunately the monthly subscriptions have gradually fallen to an insignificant amount. As a result, the recurring expenses are being met from the donations. Consequently, the sum acquired from donations has been sadly depleted and unless other sources of revenue are made available it will be very difficult, if not impossible, for the clinic to continue its existence much less make the badly-needed expansion.

It is very difficult to secure a suitable house for an institution of this nature. Most house-owners are afraid of the word tuberculosis; so we always feel a sense of insecurity of tenure. For this reason in particular, there is urgent necessity for the clinic to have a building of its own. In such an event, current expenditure will be reduced considerably and it will add to the stability of the institution.

Besides a house of its own, the clinic has other requirements, such as an ultra-violet ray apparatus, an operating table, a sterilizer, a microscope and other ordinary laboratory requisites.

Through the kind offices of Lieut.-Col. W. C. Paton, C.M.O., and the ungrudging services of Dr. S. C. Sen and Dr. A. C. W. Dessa, x-ray examinations of our patients are being done either free or at a nominal cost. The work is rapidly increasing and it is likely that in the near future these gentlemen may find it impossible to meet the demands of our work. Hence it may be necessary for us in the near future to install an x-ray set.

At present all laboratory examinations, including routine examinations, are being done by Dr. S. K. Sen, free of charge. It is too much to ask him to continue this help for long. We feel the necessity of a small laboratory of our own, equipped well enough for doing the routine examinations of sputum, urine, etc.

Preventive work.—This disease spreads mostly by direct contact. Hence the most important part of preventive work lies in tracing patients suffering from the disease, and their contacts. This task becomes easy in an outdoor clinic. Further, as these patients get treatment in the clinic, they are under some obligation to the institution, and the staff gradually gain their confidence. As a result, these patients and their relations are not likely to raise objections to us visiting their houses and adopting such measures as are deemed necessary for carrying on the preventive work.

In 1934 the clinic obtained a grant-in-aid of Rs. 1,050 from the King George Thanksgiving (Anti-Tuberculosis) Fund for this purpose. A paid lady doctor was engaged specially for this work. Unfortunately, the grant was discontinued next year on the ground that a lady health visitor was not employed for doing the work. No lady health visitor was available at that time in spite of every possible effort on our part to secure one. The services of the lady doctor had to be dispensed with for want of funds.

Subsequently, owing to the rapid increase of patients attending the clinic, the honorary staff found it impossible to pay adequate attention to preventive work. At present, excepting the distribution of booklets—'Instructions to Tuberculosis Patients'—and the giving of verbal instructions to the patients and their contacts, very little is being done in this direction.

ADRENAL CORTICAL EXTRACT IN CHOLERA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I shall be very thankful if you will please publish this letter in your Journal.

I tried adrenal cortical extract (eucortone) in a few cases of cholera with very encouraging results. As the number of cases was very few, and it is not likely for me to get a large number of cases to try the drug, I beg to suggest to those who are treating large numbers of these cases to try this drug and give their opinions. I have ample reason to believe that it may prove a very valuable adjunct in the treatment of this disease.

Thanking you,

Yours, etc.,

P. C. DUTTA,
CAPTAIN, I.M.S.,
Civil Surgeon

SHAHPUR,

PUNJAB,

1st March, 1937.

THE SIGNIFICANCE OF A HIGH INCIDENCE OF *XENOPSYLLA BRAZILIENSIS* BAKER

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the course of a rat-flea survey of a few towns in the Travancore State, I happened to note an unusually high incidence of *Xenopsylla braziliensis* Baker, particularly in one locality, viz, Athirampuzha, a typical rural inland conservancy town, situated at an elevation of about 100 feet above sea-level, enjoying a fairly warm climate. The area surveyed comprises chiefly the market, grain-stores and a few thatched houses. Six hundred and forty-three rats were trapped and 1,444 fleas were caught off them. Twenty per cent of the fleas were identified to be *Xenopsylla braziliensis* as against only $\frac{1}{2}$ per cent of *Xenopsylla cheopis*, from the same collection. For the sake of comparison and contrast, an area about half a mile from Athirampuzha and included within the same conservancy limits, consisting mainly of residential premises only, was also marked out and a survey almost in continuation of the above one showed cent per cent of *Xenopsylla astia*. It was therefore surmised that *Xenopsylla braziliensis* is not indigenous, that it thrives in close association with grain, and that its importation is the result of commercial intercourse. From the available literature at my disposal, it would appear that its distribution is very limited in Southern India, except in the Mysore plateau, where probably conditions are very suitable for its multiplication. I should therefore like to invite the opinion of your readers as to the special significance, if any, of such a high incidence of *Xenopsylla braziliensis*.

Yours, etc.,

R. SUNDARAM, M.B., B.S.,
Assistant Surgeon,
Medical Entomology,
Northern Circle.

KOTTAYAM

(TRAVANCORE STATE),
28th February, 1937.

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL E. W. C. BRADFIELD, C.I.E., O.B.E., Surgeon-General with the Government of Bombay, is appointed to officiate as Director-General, Indian Medical Service, from the afternoon of the 13th February, 1937, vice Major-General Sir Cuthbert Allan Sprawson, K.L., C.I.E., K.H.F., granted leave.

Major-General W. H. Hamilton, C.I.E., C.B.E., D.S.O., has been appointed to be Deputy Director of Medical Services, Northern Command, from 9th February, 1937, vice Major-General A. W. M. Harvey, C.B., K.H.S., retired.

The services of Lieutenant-Colonel R. E. Flowerdew, C.I.E., Inspector-General of Prisons, Bengal, are re-placed at the disposal of the Government of India on the expiry of the leave already granted to him.

Lieutenant-Colonel T. C. Boyd, Officiating Surgeon-General with the Government of Bengal, on relief, reverts to his duties as Principal, Medical College, Calcutta, from the 28th February, 1937.

Lieutenant-Colonel J. C. De, Officiating Principal, Medical College, and Superintendent, Medical College Hospitals, Calcutta, reverts to his duties as Superintendent, Campbell Medical School and Hospitals, Calcutta, from the 28th February, 1937.

Lieutenant-Colonel S. Nag, Superintendent, Mymensingh Jail, handed over charge of his office to Dr. Ananta Mohan Dutt in the forenoon of the 4th January, 1937, and the latter handed over charge of his office to the former in the forenoon of the 12th January, 1937.

Lieutenant-Colonel A. H. Shaikh is appointed Deputy Director-General, Indian Medical Service, with effect from the 15th January, 1937.

Lieutenant-Colonel H. S. Cormack, M.C., Medical Superintendent and Ophthalmic Surgeon, General Hospital, Rangoon, is appointed to officiate as Inspector-General of Civil Hospitals, Burma, vice Colonel N. S. Sodhi, granted leave.

Lieutenant-Colonel R. H. Candy, Civil Surgeon and Superintendent, B. J. Medical School, Poona, is appointed to officiate as Surgeon-General with the Government of Bombay, with effect from the forenoon of the 10th February, 1937, pending assumption of charge by Colonel H. C. Buckley.

Lieutenant-Colonel J. S. Galvin is appointed, on return from leave, as Officiating Civil Surgeon, Nasik, vice Major J. E. Gray, proceeding on leave.

The Secretary of State for India in Council has appointed to the Civil Branch of the Indian Medical Service the following officers of the Indian Medical Service, with effect from the dates stated against their names:—

Major R. C. Wats. Dated 6th March, 1936.
Major D. MacD. Fraser. Dated 22nd January, 1936.
Major J. E. Gray. Dated 1st February, 1936.
Major T. A. Doran. Dated 11th June, 1936.
Major S. Smyth. Dated 1st April, 1936.
Major G. J. Joyce. Dated 18th June, 1936.
Major J. F. Shepherd. Dated 11th June, 1936.
Captain H. Min Sein. Dated 26th February, 1936.

The services of Captain L. Dass are placed temporarily at the disposal of the Government of Madras for employment in the Jail Department, with effect from the date on which he assumes charge of his duties.

On reversion from foreign service under the Indian Research Fund Association, Captain M. L. Ahuja, an officer of the Medical Research Department, is appointed to officiate as Assistant Director, Central Research Institute, Kasauli, from the date on which he assumes charge of his duties.

Captain M. Jafar is appointed temporarily as a supernumerary officer in the Port Health Department,

Bombay, with effect from the afternoon of the 20th January, 1937.

The services of Captain R. De Soldenhoff are placed temporarily at the disposal of the Government of Bombay, from the forenoon of the 28th January, 1937.

The undermentioned appointments are made:—

To be Captain (on probation)

Alley Henry O'Malley. Dated 28th December, 1936, with seniority as Lieutenant 25th September, 1930, and as Captain 25th September, 1933.

To be Lieutenants (on probation)

Albert Matthew McGavin. Dated 28th December, 1936, with seniority 28th December, 1935.

James Douglas O'Shaughnessy. Dated 28th December, 1936, with seniority 28th December, 1935.

James Edward O'Donnell. Dated 28th December, 1936, with seniority 28th December, 1935.

Donald Robert Cattanaach. Dated 28th December, 1936, with seniority 28th December, 1935.

The following appointments are made to the Temporary Commission of the Indian Medical Service (Indian Land Forces):—

To be Lieutenants

Sleem Ahmad Mian. Dated 29th October, 1936.

Vishwanath Prasad Gupta. Dated 15th November, 1936.

Indubaran Mallik. Dated 7th December, 1936.

Mahankali Seetharama Rao. Dated 9th December, 1936.

Parshotam Dass. Dated 11th December, 1936.

Sayed Ahmad Hassan. Dated 22nd December, 1936.

Sailendra Mohon Basu. Dated 4th January, 1937.

LEAVE

Colonel N. S. Sodhi, M.C., Inspector-General of Civil Hospitals, Burma, is granted leave on average pay for 3 months, with effect from the 15th February, 1937, or the subsequent date on which he avails himself of it.

The Notification, granting leave to Lieutenant-Colonel E. C. A. Smith, Superintendent, Central Mental Hospital, Yeravda, with effect from the 5th March, 1937, is cancelled.

PROMOTIONS

Colonel to be Major-General

W. H. Hamilton, C.I.E., C.B.E., D.S.O., K.H.P. Dated 9th February, 1937.

Lieutenant-Colonel to be Colonel

A. F. Babonau, C.I.E., O.B.E. Dated 9th February, 1937, with seniority from the 2nd February, 1931.

Majors to be Lieutenant-Colonels

D. Sanyal. Dated 5th January, 1937.

S. M. A. Faruki. Dated 6th January, 1937.

B. E. Gadgil. Dated 6th January, 1937.

D. P. McDonald. Dated 9th January, 1937.

A. N. Sharma. Dated 12th January, 1937.

P. N. Basu. Dated 16th January, 1937.

J. J. Rooney. Dated 22nd January, 1937.

Lieutenant (on probation) to be Captain (on probation)

J. G. Thomson. Dated 11th November, 1936, with seniority from 1st May, 1936.

RETIREMENTS

The undermentioned officers retire:—

Lieutenant-Colonel J. J. Harper-Nelson, C.I.E., O.B.E., M.C. Dated 12th January, 1937.

Lieutenant-Colonel F. W. Hay. Dated 29th January, 1937.

RESIGNATION

Captain K. Cunningham has been permitted to resign his appointment, with effect from the 17th January, 1937, subject to His Majesty's approval.

Note

THE CORONATION

A CONSIDERABLE number of medical men will visit the home country for the Coronation, and whilst in England will naturally wish to take the opportunity to familiarize themselves with recent developments in all branches of their calling.

British manufacturers of medical equipment will most cordially welcome any opportunity they may be afforded to acquaint visitors with their latest productions.

Messrs. Watson and Sons (Electro-Medical), Limited, the well-known manufacturers of x-ray and electro-medical apparatus, desire us to make known the fact that they will be very pleased to escort visitors over their new factory at Wembley, Middlesex. This factory is equipped on most ambitious lines and is producing apparatus for the world market on a scale infinitely larger than has been attempted in the past.

Those desirous of availing themselves of this invitation should get into touch with Watsons at their London Office—Parker Street, Kingsway—when they will arrange for an escort to accompany them to Wembley.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

THE TREATMENT OF OPIUM HABIT WITH LECITHIN AND GLUCOSE

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.),
M.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

Honorary Physician to H. M. the King
and

G. S. CHOPRA, M.B., B.S. (Punjab)

(From the School of Tropical Medicine, Calcutta, Drug
Addiction Series, I. R. F. A., No. 24)

IN this paper we have recorded certain observations on the treatment of addiction to opium with lecithin and glucose which has been tried by us in the Carmichael Hospital for Tropical Diseases during the past two years. Following the lead given by our biochemical and biophysical studies (unpublished) we have treated a series of 80 patients, by the method described below, in the hospital and 120 cases in the outpatient department; these patients were taking doses of opium ranging from 10 grains to 200 grains a day. The results obtained by us have been so satisfactory that we now venture to publish them and commend them to the notice of those who have to deal with the difficult problem of getting addicts rid of this terrible drug habit.

The treatment

The procedure adopted by us was as follows :

When the patient presented himself for the treatment he underwent a thorough physical and biochemical examination. His name, age, sex, religion, occupation, social status, salary, etc., his mode of life, duration of habit, general health, weight, condition of the heart, lungs, bowels, etc., were recorded. He was told that he would undoubtedly have some discomfort, but it was impressed on him that it would not be more than he could bear, that his co-operation was absolutely essential at every stage of the treatment, and that much depended upon himself.

With a view to determining the rationale of the treatment the blood was examined for lecithin, cholesterol, blood sugar, blood calcium and for the non-protein-nitrogen contents before commencing the treatment. These examinations were repeated during the withdrawal period and after the completion of the treatment.

The condition of the heart was ascertained by taking an electrocardiograph during all the three above stages. The patients were photographed before and after the treatment in order to mark the changes in their general condition and expression. A careful record of the weight was kept throughout their stay in the hospital. The urine was examined for morphine contents daily in order to determine when the patient became drug free after withdrawal was effected. The water content of the blood plasma was

determined before, during withdrawal and after the treatment.

On the evening before the treatment was started the patient was given a dose of calomel (4 to 5 grains) followed by a saline purgative the next morning. The drug was then suddenly and completely withdrawn and the patient was watched for the development of withdrawal symptoms, which in the majority of cases started on the same day and attained their maximum within 24 hours. The actual treatment was formerly started when the withdrawal symptoms became intense and unbearable in order to study the biophysical and biochemical changes which are produced in the individual during this period. Lately it has been found distinctly advantageous to start lecithin and glucose the day before opium is withdrawn.

When these preliminary investigations were completed, lecithin (ovo lecithin Merck) was given by the mouth (Ma Wen-Chao, 1932), one pill containing 10 grains three times a day, and continued usually for five consecutive days. There is no doubt that in the majority of cases lecithin decreased the intensity of the withdrawal symptoms and shortened their duration. In spite of its administration in some of the patients the abstinence symptoms were severe and in these cases intravenous injections of 25 c.cm. of 25 per cent glucose as well as glucose by the mouth greatly helped to ameliorate the condition. These were given with a view to stacking the liver with glycogen and in order to enable it to cope with the strain, which no doubt falls on this organ, during the process of elimination of morphine and other alkaloids of opium from the system. An intravenous injection of glucose was usually given every morning for the first three or four days, and if necessary was repeated in the evening. The injections were then stopped and glucose if still required was given by the mouth. No further treatment was required after the first week. No other drug was necessary during this period except a brisk saline purgative every morning to help in the elimination of the alkaloid through the gastrointestinal tract.

The diet during this period was light because patients, as a rule, cannot take much on account of the gastro-intestinal disturbances produced by the withdrawal. Glucose, milk, and fruit juices were given freely by the mouth for the first two or three days during the withdrawal period. On the fourth day when the abstinence symptoms began to disappear and the appetite returned a diet rich in proteins and lecithin in the form of eggs, milk, beans, fish, chicken and fruits, bread and butter was given.

After the completion of the actual treatment, that is after the complete withdrawal of the drug, the patients were further kept under observation in the hospital for a fortnight or

more. A twenty-four-hour specimen of urine was examined for the presence of morphine in order to see if any one of these patients was taking the drug secretly. In the ordinary course of events the alkaloid could be detected in the urine for four to five days after the withdrawal of opium and after that they could not be detected*. If after this period the alkaloids were still found it was presumed that the patient was taking the drug. If the repeated examinations of the urine showed the absence of alkaloids it was concluded that the drug was no longer being taken and the habit was cured.

In order to effect a permanent cure we carried out a complete overhaul of every patient with a view to determining if any septic or toxic foci were present in the body, as morbid conditions of this kind are a common cause of opium addiction in this country. If routine laboratory examinations revealed such conditions, e.g., dysentery, sprue, helminthiasis, sinusitis, conjunctivitis, etc., these were treated during the period of observation after treatment.

All patients after they were discharged from the hospital were kept under observation in their homes through their friends and relatives, for a period varying from four to 12 weeks or longer in order to rehabilitate and change them to new narcotic-free environments and to watch for any relapse. They were asked to report every fortnight with a specimen of urine, which was examined for the presence of opium alkaloids. The period of rehabilitation and rebuilding of the personality of an addict may sometimes extend to six months according to the original make up of the addict. This after-treatment is very important in order to prevent a relapse and should not be neglected.

Symptomatic treatment

The following is a brief summary of the symptoms and complications which may arise in the course of treatment and how to cope with them.

*For the detection of morphine in the urine the method of Deckert (*Klin. Woch.*, 15, 697, 1937) was followed:

Ten c.cm. of the urine is heated with 0.3 gm. of Na_2CO_3 until the first bubbles rise and is then quickly cooled. It is then transferred to a separating funnel and thoroughly shaken with 10 c.cm. of acetic ether. After the layers have separated, the acetic-ether layer is transferred to a small porcelain dish through a filter-paper and evaporated to dryness on a water-bath. The residue is diluted in 0.25 c.cm. of water with one drop of nitric acid (sp. gr. 1.15) and a drop of 10 per cent ammonium molybdate solution added. After careful whirling of the porcelain dish, the contents are filtered through a compressed cotton plug placed in the upper part of the neck of a funnel. The dish is rinsed with two successive quantities of water (0.25 c.cm. and 0.15 c.cm.) which is passed through the filter. The cotton plug is then pressed down to the lower opening of the funnel, so that no filtrate remains in the funnel. A drop of 2 per cent solution of ammonium vanadate is then added and well mixed. Depending on the morphine content a turbidity develops.

(i) *Pains in the body and limbs, cramps and general malaise.*—The first two were very troublesome and often did not yield to ordinary analgesics; cramps were commonly met with but they were not very severe. Simple measures, such as massage, hot baths, aspirin and veramon, may succeed, but when the pain is severe an intramuscular injection of novalgin (Bayer) 2 c.cm. often proved effective. Hyoscine hydrobromide in 1/200 grain doses was also tried but was not found to be effective in controlling these symptoms. The pains and cramps generally disappeared in three to four days after the administration of lecithin and glucose.

(ii) *Nausea and vomiting* were common symptoms and were observed in 40 per cent of this series. In twenty cases there was actual vomiting and in two cases it was very severe and incessant. Sucking of ice greatly relieved these symptoms and in severe cases 10 drops of adrenaline hydrochloride (strength 1 in 1,000 in normal saline) under the tongue every two to four hours often gave relief.

In two patients severe bilious vomiting occurred and the stomach had to be washed out with a solution of sodium bicarbonate (one drachm to a pint of water) after which the patients were relieved.

(iii) *Constipation and diarrhoea* were treated with administration of saline every morning and if necessary calomel in half grain doses was given the previous night. Diarrhoea is also frequently met with and for this condition no special treatment is given except fluid diet and withholding the daily dose of saline. In severe cases bismuth and chalk mixture may be given.

(iv) *Cardiovascular manifestations.*—There were feeble and irregular pulse, sinking sensations, cardiac embarrassment and collapse. These symptoms were greatly relieved by administration of glucose by the intravenous route and cardiac tonics, such as brandy, cardiazol, digitofortis, etc., were effective. Special treatment for the heart condition had to be resorted to in ten cases. They were all aged persons who had been taking the drug for over 20 years and in doses above 40 grains a day and showed severe reactions during the period of abstinence. In one patient, an old man, aged 65 years, who had been taking the drug in doses of 45½ grains for a period of 40 years, collapse occurred on the fourth day of withdrawal owing to excessive loss of fluid, due to persistent bilious vomiting and diarrhoea. The treatment adopted was intravenous administration of four to five pints of glucose saline, cardiazol and atropine sulphate injections and brandy by the mouth. No opium was given. This patient was discharged from the hospital as cured after 21 days.

(v) *Vasomotor disturbances such as sneezing, coughing and running from the nose and eyes.*—Unless severe these require little or no treat-

ment but, when troublesome, a small dose of Dover's powder (5 grains) at bedtime gives relief.

(vi) *Spermatorrhœa* was treated by the following simple mixture containing potassium bromide 10 grains, ammonium bromide 10 grains, ammoniated tincture of valerian 30 minims and chloroform water up to one ounce. This mixture was given twice daily; it allayed restlessness and induced sleep. We allowed this mixture to be taken after the patient was discharged from the hospital in cases where there were signs of restlessness and irritability.

(vii) *Insomnia*.—This was a very troublesome symptom and was often difficult to treat. It generally started early in the course of treatment and sometimes continued for weeks. We often gave no treatment for this condition for a day or two, the patient being instructed to exercise his own will power and try to sleep. Sometimes he was helped by such simple measures as a hot foot bath before retiring or a dose of mixture containing bromides at bedtime. When these measures failed a pill containing $7\frac{1}{2}$ grains of medinal administered at bedtime often succeeded in producing sleep for four to six hours. This produced a real change in the patient's mental condition and attitude as he began to feel rested and gained confidence in the efficacy of the treatment. This drug should not be repeated for more than four successive nights. Other barbiturates and hypnotics, such as adaline, evipan, luminal, ortal (Parke, Davis & Co.), were tried with good results. In one serious case of intractable insomnia where nothing succeeded 30 minims of tincture of *Ranwolfia serpentina* was successful in producing sleep.

(viii) *General asthenia and loss of appetite*.—For anorexia, which was a common symptom during the first week or so, a mixture containing gentian, alkalies and nux vomica before food was very useful. The general lassitude and weakness following withdrawal were relieved by a simple mixture containing iron, strychnine and arsenic which was usually prescribed to be continued for a few weeks after discharge from the hospital.

Abstinence symptoms.—We have already stated that in order to work out the rationale of the treatment all the patients were allowed to develop the withdrawal symptoms in full before starting the actual treatment. The most common symptoms recorded during this period among the opium addicts were as follows:—

Quite a number of patients suffered from cramps which were sometimes severe, epigastric pain, sinking sensation in the chest, insomnia, diarrhœa, vomiting, headache, backache, asthenia and inability to stand up and walk. A few patients taking large doses for prolonged periods developed feeble pulse, profuse perspiration, vomiting and severe diarrhœa, resulting in collapse. Spermatorrhœa and headache were

also common. Hiccough was observed in a few cases. Vasomotor disturbances, such as sneezing, coughing and running from the nose and eyes, were also commonly seen. Palpitation and cardiac distress were also observed in a few cases. Anorexia was a common symptom and usually there was no appetite for the first three or four days and all food was refused. Over 50 per cent of the patients suffered from insomnia which was often very troublesome. We observed that there was a good deal of psychological element in all these symptoms and the addict could control, to a large extent, the intensity of the withdrawal symptoms if he was strong enough to do so.

On the second day of the actual treatment most of the patients reported that the discomfort had decreased by half. In a number of cases the patient appeared to have developed a sort of dislike for the drug. When seen a few weeks after the treatment many reported that the drug had lost all its taste and charm and in some cases the very smell of it produced the sensation of nausea. The treatment undoubtedly gave rise in a number of cases to a definite feeling of aversion for the drug, whether by smoking or taking by the mouth. There appeared to be no doubt that in a large number of cases the craving for the drug was stopped and a cure was effected.

The mental outlook of the addicts also showed a remarkable change. After the treatment the persons who came sad and morose and apathetic, with pale and sallow complexion, developed cheerful and fresh countenance, ate well and improved in general health, and put on weight. They became more social, docile and respectful and showed inclination for work. They now felt interested in their surroundings and were observed to be even more active than other patients in the hospital. After discharge from the hospital it was ascertained that most of them had become useful members of society and followed their vocations with interest.

Analytical study of the 200 cases treated

Present age of the addicts.—It will be seen from a perusal of table I that the youngest addict cured was 20 years old and the oldest who offered himself for the treatment was 70 years old. The treatment proved to be more effective in those below 50 years of age. In this series 161 or 80.5 per cent of the addicts were below 50 years of age, only 39 or 19.5 per cent were above 50 years, and none above 70 years. The majority of addicts who underwent the treatment were between 31 and 40 years of age. The age of the addicts treated and its relationship with response to treatment have been represented in table I.

It will be seen that the younger addicts of this series gave the best results. Amongst those who were completely cured, 116 or 82.9 per cent were of the ages between 21 and 50 years,

TABLE I

Showing relationship between present age of addicts and response to treatment in a series of 200 opium addicts treated

Results	NUMBER OF ADDICTS TREATED CLASSIFIED ACCORDING TO THEIR PRESENT AGES							
	20 and under	21-30	31-40	41-50	51-60	61-70	71 and up	Total
Complete cure	1	116			18	5	Nil	140
		16	77 38	23				
Dose reduced by 50 to 80 per cent	3	20 6	15	10	2	Nil	50
Failure	1	3	2	2	2	Nil	10
		161						
Total number of cases treated	1	20	100	40	30	9	..	200

18 or 12.9 per cent between 51 and 60 and only 5 or 3.6 per cent were above 61 years of age. Similarly the reduction in dosage is effected much more easily in the young than in the old. The percentage of failures is more marked in advanced age than in young adults.

Duration of the habit.—A perusal of table II will show that there were only 5 per cent in this series who had taken the drug for a period up to 5 years; 24 per cent took it for 6 to 10 years and the majority of those cured were those who were addicted to the drug for periods varying from 11 to 20 years. There were 17.5 per cent who were addicted to it for periods varying from 21 to 30 years, and 2.5 per cent from 31 to 40 years. In this series there were only two persons who had taken the drug for over 40 years.

A perusal of table II will show that the treatment although more effective in patients with duration up to 20 years also works satisfactorily in those with longer duration. The maximum period of addiction recorded in this series was 41 years in two cases which showed complete cure.

Daily dose.—The daily dose of the addicts treated has been represented in table III. It will be seen that there were only five persons who took opium in doses up to 10 grains a day, while the majority (i.e., 120 or 60 per cent) took the drug in doses ranging from 41 to 100 grains a day. There were 20 individuals (10 per cent) who took above 100 grains a day. The maximum dose recorded in this series was 200 grains *per diem*. It will also be seen that

TABLE II

Table showing relationship between the duration of addiction and response to treatment in a series of 200 opium addicts treated

the number of failures is more in the case of large doses, i.e., above 81 grains a day.

The following factors were said to be responsible for causing the habit in this series.

(1) Association or example ..	80
(2) Production of pleasure and euphoria ..	20
(3) Disease ..	100
Cough and sneezing ..	25
Asthma ..	5
Pain in joints ..	10
Spermatorrhœa ..	7
Hæmoptysis ..	2
Headache ..	12
Toothache ..	2
Piles ..	7
Diarrhœa ..	15
Epigastric pain ..	5
Watering from the eyes ..	10

Duration of treatment

The actual time taken by treatment varies according to age, physical as well as mental condition of the addict and duration of the habit. In mild cases among young persons who are physically strong and with a duration of the habit of not more than 5 to 10 years, and dosage below 40 grains a day, a cure can be effected in 10 days and the patient can be discharged from the hospital. On the other hand, in the case of persons of somewhat advanced age, i.e., above 40 years and who were constitutionally weak with a duration of the habit above 20 years and dosage of above 40 grains a day, the period of treatment may be from two to three weeks. The duration of treatment appears to depend on age, dosage and tolerance. Those with a low tolerance are relieved more quickly than those who have developed a high degree of tolerance. Likewise those with high tolerance can never be cured unless they are willing gradually to decrease the opium intake and in certain cases the reduction is very low. As a rule the average case is cured within two weeks.

Results of treatment

The results obtained in this series have been tabulated in table IV.

From the table it will be seen that complete cure was effected in 140 or 70 per cent of our series. The dose was reduced by 80 per cent in 20 or 10 per cent and by 50 per cent in 30 or 15 per cent. The treatment failed completely in 10 cases or 5 per cent of the series. So far, the results are very encouraging, i.e., 70 per cent showed complete cure.

In this series of cases there were two opium smokers and one morphine addict. Quite a number of addicts also took hemp drugs and alcohol in addition to opium. That the treatment was popular is shown by the fact that addicts came from remote parts of India to Calcutta for getting rid of the habit.

Summary

1. A method of treatment of opium habit with lecithin and glucose tried in a series of 200 cases has been described.

2. The percentage of cure effected works out to 70. The results obtained are so satisfactory as to warrant a more extensive trial.

3. The lines of treatment are simple and may be tried in the addict's house if his faithful co-operation is ensured.

4. The cost of treatment is reasonable and it can be tried for mass treatment.

ANÆMIA IN TEA-GARDEN LABOUR FORCES

By L. EVERARD NAPIER, M.R.C.P. (Lond.)

*Acting Professor of Tropical Medicine
Calcutta School of Tropical Medicine*

[This paper gives a short account of work carried out by the writer and his assistants in Calcutta and in Assam. The writer is a worker under the endowment of the Calcutta School of Tropical Medicine, but some of the work reported was financed by the Indian Research Fund Association.

The paper, in very much the same form, was read at the Annual General Meeting of the Assam Branch of the British Medical Association in January 1937.

A more complete account of this work will be found in the *Indian Journal of Medical Research*, volume XXII, p. 809, volume XXIII, pp. 305, 311, 455 and 973, volume XXIV, pp. 855 and 1159.]

In investigating the anæmias of tea-garden coolies, the first difficulty that we encountered was the complete absence of any reliable hæmatological data in the form of normal standards for Indians and in supplying these we were able to expose some popular misconceptions and to make a few observations that have not yet been fully explained; of the former the most striking was that the blood of the healthy well-nourished Indian is not 'thin', the hæmoglobin in the male being about 110 to 115 per cent. .

preferably 100, divisions, and an anticoagulant, e.g., potassium oxalate.

Blood is withdrawn from a vein, a definite, but not necessarily an exact, amount, say 5 c.cm.; this is put into a tube containing powdered oxalate—0.01 gramme for 5 c.cm. of blood. The blood and oxalate are mixed by spinning the tube between the palms of the hands. The oxalate blood is transferred to the graduated tube up to the top mark and centrifuged for 20 minutes. The level of the red cell is read off as a percentage of the whole and is multiplied by a factor, 1.09, to compensate for shrinkage of the cells. The normal is from 44 to 48 per cent.

Three other values are calculated :—

The mean corpuscular volume (MCV)

$$\frac{\text{Volume of packed cells per 1,000 c.cm.}}{\text{Red cells per c.mm. in millions.}}$$

The mean corpuscular hæmoglobin (MCH)

$$\frac{\text{Hæmoglobin in grammes per 1,000 c.cm.}}{\text{Red cells per c.mm. in millions.}}$$

The mean corpuscular hæmoglobin concentration (MCHC)

$$\frac{\text{Hæmoglobin in grammes per cent} \times 100.}{\text{Volume of packed cells per cent.}}$$

Normal European standards.—

MCV 87 cubic μ

MCH 29 $\gamma\gamma$

MCHC 33—35 per cent.

Normal Indian standards.—The means of a number of observations are given below :—

TABLE I

	Calcutta males	COOLIES		Pregnant females
		Males	Females	
Hæmoglobin, in grammes per 100 c.cm. ..	15.70	{ 11.83 } { 12.63 }	{ 10.03 } { 11.30 }	10.7
Red blood corpuscles, in millions	5.53	{ 5.35 } { 5.27 }	{ 4.55 } { 4.93 }	4.65
Cell volume, per cent	50.53	36.63	35.10	32.8
Mean corpuscular volume, cubic μ	90.49	71.29	72.30	72.1
Mean corpuscular hæmoglobin, $\gamma\gamma$	28.53	23.93	23.35	23.8
Mean corpuscular hæmoglobin concentration, per cent	31.07	32.50	33.07	30.3
Number of observations on which means are based ..	30	24 and 18	17 and 16	40

At this point I think that I will explain a few terms that I shall use :—

Hæmoglobin.—The expression 100 per cent is really meaningless, as it may indicate anything from 13.8 grammes to 17.2 grammes per 100 c.cm. of blood. We therefore refer to hæmoglobin in grammes per 100 c.cm. of blood.

Cell measurements.—The halometer gives very misleading results, and the Price-Jones method is too laborious for routine use, so we used the packed-cell method for estimating cell volume; this requires an electric centrifuge that will do 2,000 revolutions at least, a small graduated tube with at least 50, and

Anæmic coolies from the general population

We did a fairly complete hæmatological examination of 100 anæmic coolies selected from the general coolie population. They were selected clinically; a Tallqvist reading, taken by the assistant medical officer on the garden, below 50 per cent was taken as the criterion. They were examined in two groups, 58 in the first year; in these a subsequent examination was carried out after an interval of a few months, but no special treatment was given. The coolies were, however, given the usual routine anthelmintic treatment and put on ordinary

iron mixtures, but as most of them were out-patients, they probably took very little of this. The second group of 42 patients (subsequently reduced to 41 by a coolie absconding) was divided into six different groups, and each group was treated differently, but all were given an adequate course of ferrous sulphate.

The pre-treatment findings in the second series

I will not attempt to go into these in detail, but I will give a few figures from the data collected. The lowest hæmoglobin level was 2.5 grammes, and the mean corpuscular values were as follows :—

The conclusions at which we arrived in connection with these two series were as follows (I am quoting from a recent paper*) :—

With very few possible exceptions the anæmia was of the microcytic-hypochromic type.

In no instance was the anæmia of the pernicious type.

The response to treatment with large doses of iron in 39 out of 41 cases in the second series makes it evident that this microcytic-hypochromic anæmia is an iron deficiency anæmia.

TABLE II

	Males	Females	All cases
Mean corpuscular volume (MCV)	65.75 cu. μ	72.60 cu. μ	69.72 cu. μ
Mean corpuscular hæmoglobin (MCH) ..	16.17 $\gamma\gamma$	18.06 $\gamma\gamma$	17.23 $\gamma\gamma$
Mean corpuscular hæmoglobin concentration (MCHC)	25.62 per cent	25.60 per cent	25.61 per cent

This chart (chart I) represents the individual values; it will be seen that there is hypochromia in every instance and that the vast majority are microcytic as well, none being truly macrocytic.

The cause of this iron deficiency. Actual deficiency in the diet.—It is hard to make any estimate of the iron content of the coolies' diet.

* *Indian Journ. Med. Res.* (1937), Vol. XXIV, p. 855.

CHART I

Showing the relationship between the mean corpuscular volume and the mean corpuscular hæmoglobin in 38 cases in the second series.

It is possibly poor in iron but there is strong evidence to suggest that it is richer in iron than that of many non-anæmic vegetarian communities; the absence of milk and the low fat consumption are the two most striking features in the coolie dietary. The water in the district contains a large quantity of iron, but the iron is in the ferric state.

Failure of absorption.—The fractional gastric analyses in 87 cases showed the presence of free hydrochloric acid in 80 cases without the administration of histamine. The incidence of achlorhydria is, thus, lower than in the normal population and the possibility that the iron deficiency is due to failure of absorption on this account is ruled out.

Hookworm infection.—A hookworm infection was demonstrated in nearly every case; in half the cases the hookworm infection was a heavy one. The type of hypochromic-microcytic anæmia from which these patients were suffering is, broadly speaking, the anæmia that is usually associated with hookworm infection.

An examination of random samples of stools taken from the normal coolie population shows almost a hundred per cent infection rate, but only about 14 per cent with a heavy infection (10,000 eggs or more per gramme).

On the other hand, we were unable to show any association between the degree of hookworm infection, as demonstrated by the egg-counts, and the degree of the anæmia.

The actual presence of a heavy infection does not prevent the hæmoglobin from recovering to a point above the normal level of the coolie population, nor does the persistence of a heavy hookworm infection appear to affect the degree of improvement in individual cases. But in the garden in which the treatment was least effective (Murmuria) the hæmoglobin level tended to fall during the last two months of observation, whereas in another garden (Nagadholie), in which the iron and dietary treatment had been almost the same but the hookworm treatment had been effective, the hæmoglobin continued to rise.

We can summarize our observations by saying that hookworm infection is almost certainly the main factor in the production of anæmia but that, as a normal hæmoglobin level is not incompatible with a heavy hookworm infection, there is probably some other factor that determines why anæmia occurs in some cases and does not in others.

Associated factors in the production of anæmia. Malaria.—The spleen index on the garden from which the coolies came varies from 28 to 39 per cent. The spleen was palpably enlarged in about one-third of the cases, but there is no correlation between the splenic enlargement and the degree of anæmia.

In more than a third of the cases there is hyper-bilirubinæmia; this is not a usual finding in simple hookworm anæmia. It suggests, either

(a) that there is some liver dysfunction, which seems unlikely as there is little other evidence of this, (b) that there is excessive hæmolysis, or (c) that the products of normal hæmolysis are insufficiently re-utilized, because of a deficiency in some other substance essential to normal hæmopoiesis.

Excessive hæmolysis suggests concomitant or recent malarial infection, and it does sometimes occur in cases of chronic splenic enlargements; in the first series, there was a comparatively high correlation between hyper-bilirubinæmia and splenic enlargement; this correlation was not however statistically 'significant', nor in the second series was there any evidence of such correlation.

Hyper-bilirubinæmia occurs in pernicious anæmia, where it is due to deficiency of the hæmopoietic principle, but does not usually occur in iron deficiency; if therefore the suggestion (c) above is to be valid there must be some other deficiency. In the second series, the incidence of hyper-bilirubinæmia is considerably reduced following treatment; this fact lends support to the suggestion that it was due to incomplete re-utilization of the products of normal hæmolysis.

The anæmia associated with either acute or chronic malaria does not present the picture of the anæmia with which we are dealing; as in malaria there is only intravascular or intracellular destruction of blood, there is not the same loss of iron from the body that occurs in hookworm anæmia.

Diet.—Though none of the coolies are indigent and all earn sufficient money to provide themselves and their families with an ample diet, there is little doubt that the diets on which they live are ill-balanced and deficient in good protein and in fat; there is little evidence of any vitamin deficiency except possibly of vitamin A.

An experiment was designed to see the effect of diet on the blood picture. Eight patients were kept for a period of 28 days on a well-balanced diet with a caloric value of about 3,500. In no one case did the blood picture improve and the mean hæmoglobin in the series was slightly lower at the end of the period (chart II). These patients were then given large doses of ferrous sulphate for three weeks and there was an immediate response; there was a mean increase of 6 g. in the hæmoglobin of the eight cases within a period of 28 days.

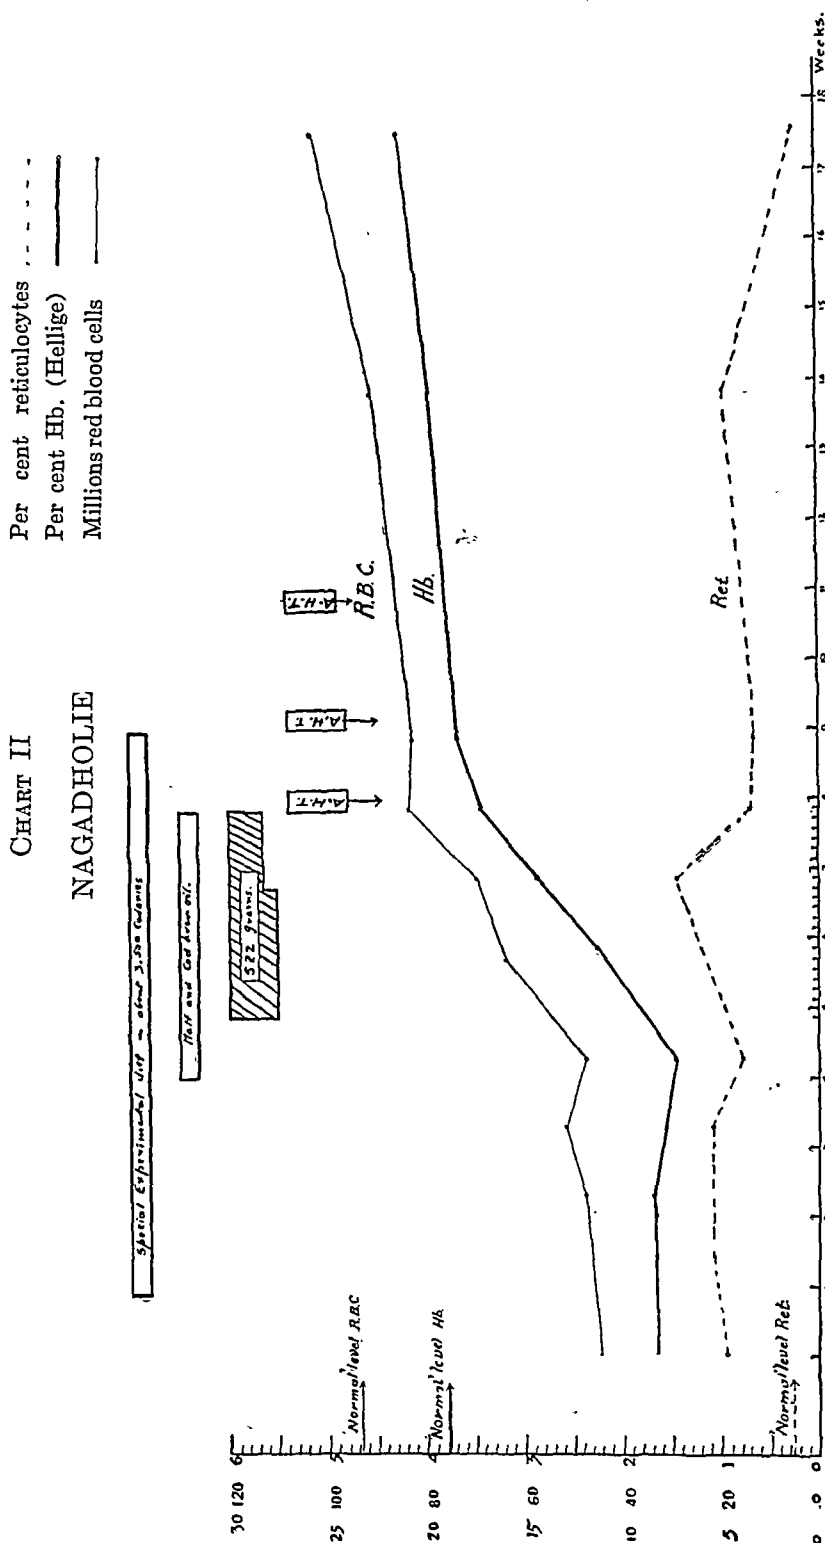

This experiment shows that dietary re-adjustment by itself will not effect an immediate improvement in the blood picture in cases in which anæmia is established. It does not, however, prove that a deficient diet does not produce a state in which the patient is susceptible to a degree of blood loss that in more favourable conditions would be easily compensated.

We must, however, conclude from the evidence here produced that dietary deficiency is not an

important factor in this particular type of anæmia.

The unknown factor limiting the final hæmoglobin level.—We have shown that, although in

Even starting from the higher hæmoglobin level of the 'normal' coolie, improvement beyond a certain point seems to be unattainable. If we look at the corpuscular values after treat-

Showing composite curves based on the findings in seven cases, one male and six females; in calculating the 'normal' levels in this and the subsequent figures the sex composition of the group has been taken into account.

(The shaded block indicates the period of ferrous sulphate administration. A.H.T. = anti-helminthic treatment.)

nearly all the cases there was a marked response to treatment, there is some limiting factor which prevents improvement beyond a certain level, and that this level is not the level of the better-class, city-dwelling Indian.

ment it will be seen that the MCH and MCV are far below the normal, but that the MCHC approximates very closely to the normal. That is to say, the provision of iron has brought the cell contents up to the usual hæmoglobin

concentration, but there is still some factor which interferes with the blood-cell formation at the normoblastic level.

This deficiency, if it is a deficiency, appears to be common to the whole coolie population as the MCH of the first series of 'normal' coolies (22.2 $\gamma\gamma$) was even less than it is in this series.

The main factor in the production of anæmia in hookworm infection is the loss of blood and all its constituents. Iron is obviously a vital constituent and supplying this will bring the blood up to a certain level, but, in the circumstances of the above experiments, not back to normal.

In the anæmia following malarial infection the loss of blood is from the circulation and not from the body. In the process of hæmolysis the iron is saved and stored; we know something of the subsequent course of the blood pigments, but we know little about the fate of the other blood elements, and we do not know whether certain of these, that are not easily synthesized in the body and whose products are not stored, are not broken down during the process of hæmolysis.

Finally, though we have been unable to show that the anæmia can be cured by the provision of a good diet, we cannot be certain that long periods of deficient diet have not reduced the store of some essential factor for normal hæmopoiesis, so that the body is unable to meet the extra demand which is thrown on it by the long-continued blood loss of hookworm infection, and/or by blood destruction in repeated malarial infections.

The results of different treatment procedures

The total dose of iron.—The mean improvement during the first month was fairly constant in the first five groups and bore little relationship to the total iron dosage, but on the three gardens where the highest dosage was given the improvement was maintained.

This is a point that I have studied further in my ward cases in Calcutta. I always give a three weeks' course of 18 grains a day (378 grains) in the first instance and I have found that in about half the cases a further course is indicated and when given pushes the hæmoglobin level higher.

The results with the smallest dosage, 11 grains a day for three weeks, were very satisfactory indeed compared with those of treatment by anthelmintic and ordinary iron tonics, that was given in the first series.

The effect of diet.—The two groups in which a special diet was given were unfortunately those in which the largest dose of iron was also given, but these results were not quite as good as in the Katinibari group where no special diet was given, though the normal hospital diet is a good one. In the Sycotta group, where a very adequate dosage of iron was given and where the effect of hookworm treatment was very satisfactory, there was an early falling off in the

hæmoglobin level, and in the Kharikatia (b) group, where the diet was unsatisfactory, the results were poor; the results in these two groups do suggest, but not very forcibly, that diet has some effect on the maintenance of a high hæmoglobin level.

Hookworm treatment.—In the first series where for all practical purposes only hookworm treatment was given, except to those treated as hospital patients, the results were far below the worst results in the second series. It is therefore apparent that anthelmintic treatment alone will not effect a cure except possibly after a long interval.

It is quite obvious that almost maximal improvement can be achieved without anthelmintic treatment, and that in the presence of a heavy hookworm load a high hæmoglobin level can be maintained for some months (*vide* Murmuria). On the other hand, it is quite certain that in time the hookworm infection will cause a recurrence of the anæmia; for example, in the Kharikatia (b) group, where a heavy infection was maintained, there was a marked fall in the hæmoglobin level even during the short period of observation of this experiment.

It seems to be a matter of little importance whether the anthelmintic treatment is given before or after the iron treatment from the point of view of the eventual result, but there are certain advantages in giving the treatment to a healthy rather than to an anæmic individual. In this investigation, some of the best results were achieved by giving the anthelmintic treatment first but so also were the worst results [*vide* Katinibari and Kharikatia (b), respectively].

A table summarizing the results of the different treatment procedures is given below.

'Normal' pregnant women: another control series

A series of 40 non-anæmic pregnant women was examined during the next year; the important data are given below, and also in table I.

Pregnant women

The next series that was investigated were 228 pregnant women taken from the 'pregnancy' parades. In this instance only the hæmoglobin was estimated, but this was done with some precision, usually in duplicate, with the Hellige apparatus.

The mean hæmoglobin of the series was 9.22 grammes, which is slightly but distinctly lower than the means in the two normal (female) coolie series, 10.03 and 11.30, respectively, but to obtain these latter figures we excluded all coolies below the 50 per cent level, as we considered these not normal but definitely anæmic; if we take the same arbitrary level we can divide these coolies into two groups, the anæmic group consisting of 36 women (that is to say, 15.8 per cent) and the 'normal' group of 192 women.

TABLE III

Summarizing results of treatment on different gardens

Group	Cases	Diet in calories approximately		Iron in grains	ANTHELMINTIC TREATMENT		MEAN HÆMOGLOBIN LEVEL AND TOTAL INCREASE, BEFORE, AND AFTER DIFFERENT PERIODS FROM COMMENCEMENT OF IRON TREATMENT			
					Before or after iron	Number of final egg-counts above 5,000	Before iron	A month	About two months	About three months
Nagadholie ..	7	Good	3,500	522	After	1	4.0	$\frac{10.1}{6.1}$	$\frac{10.9}{6.9}$	$\frac{11.7}{7.7}$
Murmuria ..	8	Good	3,500	540	After	5	3.9	$\frac{10.3}{6.4}$	$\frac{11.8}{7.9}$	$\frac{11.3}{7.4}$
Sycotta ..	6	Ordinary	2,200	360	After	0	5.1	$\frac{11.5}{6.4}$	$\frac{11.7}{6.6}$	$\frac{11.0}{5.9}$
Katinibari ..	6	Good	2,500	478½	Before	1	4.6	$\frac{11.4}{6.8}$..	$\frac{13.0}{8.4}$
Kharikatia (a) ..	5	Ordinary	2,200	231	After	1	4.2	$\frac{10.2}{6.0}$..	$\frac{10.0}{5.8}$
Kharikatia (b) ..	4	Poor, less than 2,000		275	Before	3	4.0	$\frac{9.1}{5.1}$..	$\frac{7.7}{3.7}$

TABLE IV

Forty normal women (pregnant)

	Maximum	Minimum	Mean	Standard deviation
Hæmoglobin in grammes per 100 c.cm. ..	12.51	9.62	10.7	± 1.6
Red blood cells in millions ..	5.96	3.68	4.65	± 0.62
Cell volume ..	37.8	29.0	32.8	± 2.3
Mean corpuscular volume ..	90.2	59.4	72.1	± 8.1
Mean corpuscular hæmoglobin ..	29.5	18.2	23.8	± 2.9
Mean corpuscular hæmoglobin concentration ..	39.2	27.8	32.6	± 1.8
Reticulocytes ..	4.7	0.4	2.1	± 1.8

The mean hæmoglobin of the 'normal' group was 9.99 grammes which is remarkably near the figure 10.03 grammes which we found in the first series of the general female population. Amongst the general female population the incidence of definite anæmia (*i.e.*, below 50 per cent, or 6.9 grammes) was less than 10 per cent, so that there are obviously more anæmics amongst the pregnant women, although, if anæmics are excluded, the mean hæmoglobin level does not seem to be lowered by pregnancy. Further, there is no evidence of any progressive hæmoglobin deterioration throughout pregnancy. The anæmia is more frequently encountered in younger women and in the first pregnancy; these two facts are obviously interdependent.

Next, 52 pregnant anæmic women were examined, but in these a much more complete examination was carried out and in some a

second examination was made after delivery. These results have not been fully analysed yet, but there are certain points about the findings in this group that are of interest. These 52 cases can be divided into four groups:—

- (a) Hyperchromic. Markedly anæmic 8.
- (b) Ditto. Slightly anæmic 10.
- (c) Orthochromic. All moderately anæmic 6.
- (d) Hypochromic. A continuous group, all degrees 28.

If the cases were divided according to the size of the cell, they would fall into corresponding groups, with a few minor exceptions; that is to say, the 18 hyperchromic cases were also macrocytic, and the 28 hypochromic were microcytic.

The chart shows these graphically.

CHART III

Showing distribution of 40 'normal' and 52 anæmic pregnant females according to their hæmoglobin percentages and mean corpuscular hæmoglobin.

The orthochromic (normocytic) cases were probably mixed microcytic and macrocytic cases, but leaving these out of consideration we see that the rest are roughly two-fifths macrocytic and three-fifths microcytic, and, if we compare this analysis with the anæmics in the general population, we see that the macrocytic group is quite a new element that seems to have come in with the pregnancy.

Now in this series we undertook no treatment and only followed up a small number of the cases; of those who were examined a second time, after delivery, all the microcytic ones had maintained their microcytic nature and most of the others showed a tendency towards the microcytic side. That is to say, the macrocytic tendency seemed to disappear with the termination of pregnancy.

It is obvious that we must know more about how these pregnant anæmics react to different forms of treatment, and we are now examining a series and following up each case as long as practicable. I think that my assistant has now done about 40 cases in this series, but I have

only received particulars of about 24, and I have not yet analysed these fully. It is of some interest that of these 24 cases only six are microcytic. This finding of 25 per cent microcytic against 60 per cent in the last pregnant series seems to require some explanation. The cases are from a different district and we may find that this provides the explanation, but I have another suggestion to put forward: this last group of cases is from Dr. Fraser's practice and for a year or so he has used ferrous sulphate very freely. It seems to me possible that he may have eliminated the majority of his microcytic anæmias by the use of iron and that therefore the residue is mainly the macrocytic and normocytic groups.

Going through these cases, I find that the results of treatment have been singularly disappointing and that in the presence of the fœtus little improvement has occurred, whatever the treatment given. In no cases has marmite had any beneficial effect and in very few has liver extract produced any dramatic improvement or a reticulocyte response. After delivery most

cases have improved whatever treatment was given or even in the absence of any specific treatment.

I am not in a position to make any recommendations regarding the treatment of anæmic pregnant coolies. Though I know I am saying something which must be quite obvious to every one, the best hope seems to be in prevention rather than cure. That is to say, one should see that all anæmic females are treated in the early days of their pregnancies when they are mostly suffering from microcytic anæmias that respond well to treatment by iron, because I believe that there is some evidence that these microcytic anæmias become macrocytic in the later months of pregnancy, and then they are extremely resistant to treatment even with that expensive substance, liver extract.

Macrocytic anæmia due to general dietary deficiency

There is just one other point that I should like to bring up in connection with anæmia in Assam and elsewhere. There seems to me to be little evidence that even the macrocytic anæmia in Assam is the tropical macrocytic anæmia described by Dr. Lucy Wills. There is little evidence of vitamin-B deficiency in the dietary, and there is still less evidence that vitamin-B substances will effect a cure. In Calcutta, we have found that marmite has a specific effect in certain cases, but we have also found that some patients improve on a rich mixed diet in which there is no excess of vitamin B. At present we are attempting to find out what is the special food factor that produces this change.

I will show you the charts (charts IV and V) of two cases and will remind you of the experi-

CHART IV

ment that we did up here with eight cases of microcytic anæmia (chart III); the contrast is very striking.

Both these patients were of the coolie class and on investigation were found to be living on a very deficient diet, consisting mainly of rice. In hospital they received the hospital diet, which is a good mixed diet of about 3,000 calories. In one patient the improvement was

CHART V

from 3.5 grammes to well over 10 grammes within a period of a month, and he reached about 12 grammes without any medicine whatsoever. In the second case, the rate of improvement was a little slower and it ceased at about the 10-gramme level; liver extract was then given in both cases and there was another sharp rise. In the second case the cells had been very large and still remained well above normal until the liver extract was given; then the size fell to the usual level.

Both these patients were suffering from some dietary deficiency which hospital diet supplied almost wholly in one case, but in both liver extract caused a further sharp rise which suggests that this substance was able to supply something that ordinary diet did not.

It will be remembered that in the eight microcytic cases there was no improvement at all on

(Continued at foot of next page)

A SHORT NOTE ON THE USE OF PNEUMONIA STOCK VACCINE IN THE TREATMENT OF THE PNEUMONIAS*

By G. FRASER

Labac Central Hospital, Dewan P. O., Cachar

THE investigation into pneumonia in Assam has been going on for the last two or three years and at our 1935 meeting Dr. Napier disclosed a few interesting facts regarding the types prevalent here up to that time.

Direct typing, mouse inoculation, and cultural methods were used.

Five strains were identified as hæmolytic streptococci and 60 strains as pneumococci. Of the 60 pneumococcal pneumonias 15 were broncho- and 45 lobar pneumonias.

The recognized fixed types I, II and III were poorly represented but a large number was of an apparently virulent type, not identifiable with any sera in their possession; this he provisionally called B; there was another uncommon type not associated at that stage with any mortality which he called A.

It was supposed, then, that commercial stock serum would not be of much use in treatment in these districts.

Last year, at this meeting, I suggested that in view of the expense of serum and the difficulties such as typing, repeated intravenous injection especially in children, thermal reactions and rigors and the limited efficacy even with the commercial polyvalent serum which is, at the same time, more expensive, a trial should be given to the simpler vaccines, and that the Calcutta School of Tropical Medicine might proceed to produce a vaccine from the types

* Being a paper read at the Annual General Meeting of the British Medical Association, Assam Branch, in January 1937.

(Continued from previous page)

a rich diet, but immediate improvement on iron administration (see chart III).

Acknowledgments.—I will take this opportunity to acknowledge the invaluable assistance given to me and my assistants by Dr. David Manson of Cinnamara, Dr. George Macdonald of Mariani and Dr. George Fraser of Labac. The data reported are taken from coolies in their practices and without their interest and co-operation it would have been quite impossible to do this work.

Most of the actual blood examinations were carried out by my assistants, Doctors C. R. Das Gupta, H. S. Bilimoria and D. N. Mazumdar, whose names are, or will be, associated with mine in the fuller reports on this work that have appeared in, or will be submitted for publication to, the *Indian Journal of Medical Research*.

encountered by Dr. Napier on the lines of Prof. Wynn's P. S. I. formula. Dr. Napier in due course very kindly prepared such a vaccine.

The vaccine is a plain emulsion made from young primary cultures and sterilized by heat. The vaccine must be active and of known antigenic power; any great degree of subculturing causes loss of smooth, virulent organisms, and therefore loss of active antigenic power. The aim is to obtain an immediate non-specific effect, developing after this a specific effect, and for the latter purpose this vaccine is composed of the particular pneumococcal types encountered, here provisionally called A and B, plus the hæmolytic streptococci also encountered. Prof. Wynn in his formula also has *B. influenzae*, but at present this has not been incorporated in our vaccine.

The principle is that of vaccine generally. In pneumonia particularly the curve of intoxication rises rapidly and then remains at a high level. Specific antibodies are at first absent but begin to appear about the fourth or fifth day; the curve rises slowly at first, then rapidly, reaching a maximum at about the seventh day, when in a favourable case a crisis will occur. The object is to hasten the production of antibodies. Antibodies are specific in pneumonia as in other diseases and these specific antibodies are produced only after a few days. There is an immediate effect however in the stimulation of non-specific antibodies—an immediate outpouring of bactericidal substances. This form of immunity is first exploited, and reinforced in due course by specific immunity and it is for this last purpose that it is desirable that specific-type organisms be used in the production of the vaccine. It is essential that the therapy be commenced early before toxin becomes fixed in dangerous amount in heart and nerve cells, and while leucocyte response is vigorous. At this stage, too, the patient is unsensitized and can react promptly and can control or even abort the disease. In, for instance, unresolved pneumonia or any chronic infection he is sensitized and only gives unpleasant and unfavourable reactions. These are general principles but I borrow them as a reminder from an article by Prof. Wynn.

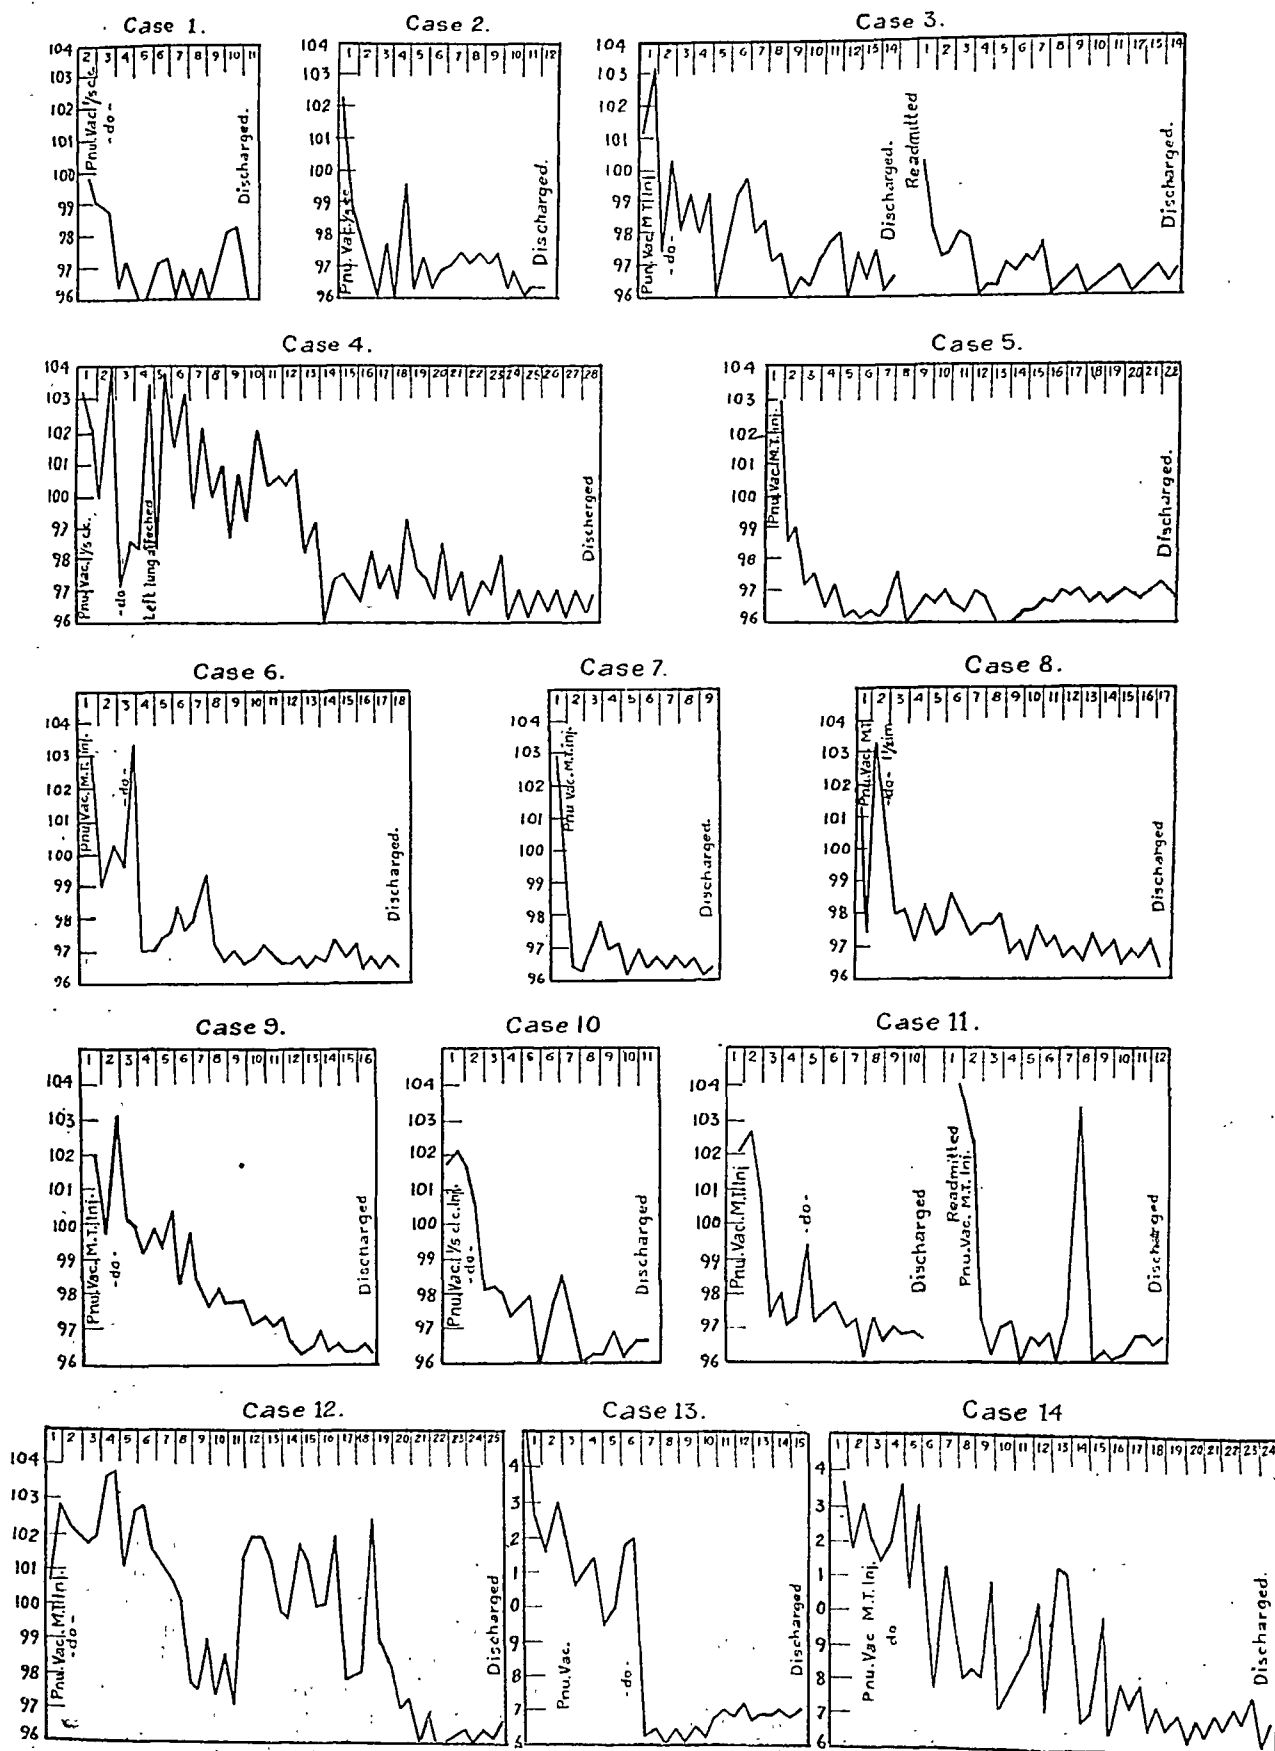

A suitable dose is 200 million of each of the organisms and proportionately less for children. It can be repeated every 24 hours for three days.

I have been using this vaccine since last May and have brought here some charts and case sheets for your perusal. You will see from these the precipitate fall of temperature in many cases and the rapid rise in leucocyte count. Many of these cases were found to have pneumococci in their sputum. More striking than anything was the clinical appearance in so

Temperature charts in cases of pneumonia treated by vaccine.

many cases. It is common one day to see the patient very distressed and anxious with high temperature and rapid pulse and respiration, and next day after vaccine administration his temperature has fallen to normal, pulse and respiration are quiet and within normal limits and he looks placid and feels better, yet on examination he will be found to have a portion of lung consolidated and to be expectorating pneumococci. It is suggested that the vaccine may hasten the consolidation and evolution of the pneumonia phases generally. Even if the temperature does not come down the patient commonly admits to feeling better, his tongue is moist and he looks fairly cheerful and the general impression is that he is going to do well.

Broncho-pneumonias respond in the same satisfactory way in my experience.

I have seen the same thing happen from time to time with S.U.P., and I have no doubt many here have also done so and some may say they have seen sudden defervescence and clearing up of a pneumonia with no particular form of therapy at all. What I feel is that with this vaccine I am using there is a satisfactory clearing up of the disease at an early stage *more frequently* than with any form of treatment I have hitherto used.

My experience of this vaccine is limited to a very short series of cases, too few perhaps to be very convincing—23 with this pneumonia stock vaccine of which one died, an old man of 75, who came seven days late and was already at death's door. The progress in these cases can be best appreciated by reference to the table and temperature charts.

There is a series of cases treated with S.U.P. in which there were three deaths in 26 cases. It would be unfair to compare these, as most of the vaccine series had come in the early stages; for example, 13 one day late only and 6 two days late, whereas the S.U.P. series had 3 one day late, 4 two days late, 5 three days late and 11 four or more than four days late.

I am convinced from my own observations that an improvement in results is obtained with this vaccine. It is, however, very desirable that others also give it a trial so that its value may be properly assessed. If its efficacy is confirmed it will be a simple and cheap remedy.

I have used it only at my central hospital so far, so as to obtain a proper estimate of its value first hand, but I am now releasing it for use at the garden hospitals, which, of course, nurse their own pneumonias.

I am very grateful to Dr. Napier for taking the trouble to make up this vaccine and I am sure if any one is interested he will be pleased to give him some for trial.

THE OPERATIVE TREATMENT OF VESICO- AND VESICO-URETHRO VAGINAL FISTULÆ BY THE VAGINAL ROUTE WITH CASE NOTES ON THIRTY-THREE CASES

By S. N. HAYES, F.R.C.S., F.C.O.G.
MAJOR, I.M.S.

Professor of Obstetrics and Gynæcology, King Edward Medical College, Lahore, and Medical Superintendent, Lady Willingdon Hospital, Lahore

THERE is no more distressing complication of labour than a vesico-vaginal fistula—converting, as it does, a normal healthy girl into a wretched creature whose life is a perpetual misery, and who is willing to undergo any operation to be free from the constant dribbling of urine, or who, as so many patients have said, would rather die than continue in her present condition.

Although small fistulæ can easily be cured, the larger ones presumably present certain difficulties, as evidenced by the number of cases one sees on which several operations have been performed, each one causing increased fibrosis, until ultimately there is no alternative possible except transplantation of the ureters.

Since 1931, sixty-three cases of vesico- and vesico-urethro vaginal fistulæ have been operated on at the above hospital—thirty-three by the vaginal route, of which twenty-eight were cured, two partially cured, two failed, and one died of blackwater fever.

It is noteworthy that the failures occurred in the early cases and were undoubtedly partly due to lack of experience.

This paper describes the technique that has been gradually evolved at this hospital and found satisfactory. As experience accumulates, larger and larger fistulæ are being attempted and cured, and it is hoped that in the near future it will be possible to describe a technique that will result in a very high percentage of cures without having to resort to transplantation of the ureters.

Ætiology

The causes in this series are thirty cases following labour, one case due to trauma—a wooden stick, which was being inserted into the uterus to procure an abortion, was pushed through the vaginal wall into the bladder (case 10).

The majority of cases give a clear history of prolonged labour and early rupture of the membranes. It is most probable that the commonest cause of obstruction was an unreduced occipito-posterior position, with the following results—the bladder becomes distended, the urethra elongated, the sinciput presses the base of the bladder and upper part of the urethra against the symphysis pubis, pressure necrosis ensues, and after exfoliation of the necrosed area the fistula results.

Classification

Fistulæ vary so considerably that any accurate attempt at classification is impossible.

From the operative point of view, they fall naturally into two classes :—

- (1) Simple.
- (2) Complicated.

(1) Simple fistulæ vary in size from a pin-hole to about half an inch in diameter. (Beyond this size the urethra is usually involved or fibrosis is excessive.) They are generally centrally situated and involve the anterior wall of the bladder. Fibrosis is absent or slight, and the cervix and uterus are mobile. The urethra is not involved.

(2) Complicated fistulæ are usually larger than half an inch in diameter. Fibrosis and cicatrization are present to a varying degree, from slight to a one-finger contraction of the vault and lumen of the vagina. The bladder is frequently bound down to the posterior surface of the symphysis pubis, and laterally to the rami of the pubes. The urethra is usually involved—from destruction of a small portion of its upper end, to complete destruction. Out of sixty-three fistulæ, the urethra was involved in thirty-two. The bladder mucous membrane may be prolapsed into the vagina. The base of the bladder is involved causing destruction of the sphincter.

The cervix is often not visible, either through destruction or by a transverse barrier of fibrous tissue of cartilaginous hardness in the upper part of the vagina. The uterus is usually fixed.

Choice of operation

I, personally, consider that the vaginal route is the operation of choice. Surprisingly large fistulæ can be cured by this route, and the patient is returned to her normal condition. As no operations have been performed by the supra-pubic route, no opinion can be expressed on this method. The method is attractive in theory, and could be combined with a vaginal operation. In future, it is intended to use it for cases in which the vaginal method has failed. Although thirty cases of transplantations have been done, I consider that it is an operation that ought only to be done when all other methods have failed. Reasons will be elaborated in a future paper on transplantation operations. A combination of either supra-pubic and/or vaginal operation would probably have sufficed in quite a number of the thirty cases of transplantation operations.

A method of treating small inaccessible simple fistulæ by diathermy has recently been described. This method can only be applicable to very small fistulæ, and we also know by experience that a very large percentage of small fistulæ will heal spontaneously or to the treatment of an indwelling catheter.

Signs and symptoms

Dribbling of urine is the chief symptom. When a recto-vaginal fistula is present, the complaint is the passage of urine and faeces per vaginam.

The vulva is usually excoriated, and this may spread down the inner side of the thighs and legs to a varying degree.

As a well-marked cystitis is present, fever is frequently complained of.

Treatment of recto-vaginal fistulæ

Out of sixty-three cases, recto-vaginal fistula was present in six.

It is important that these fistulæ should be closed before any attempt is made on the vesico-vaginal fistula.

They usually present no difficulty. Schuchardt's incision (described later) or a median episiotomy is often necessary in order to ensure adequate access. The rectum is then freely mobilized and the fistula closed with double 00 catgut Lembert's sutures. The vaginal mucous membrane is closed with a continuous no. 1 catgut suture.

Pre-operative treatment for vesico-vaginal fistulæ

The object in view is to clear up any cystitis present, and to provide an operation area as clean as possible.

(1) Bladder washouts of boric acid are given once or twice daily.

(2) Sitz baths twice daily.

(3) An ointment of zinc oxide and lanoline is applied to the labia.

When the bladder and wound are clean, an ounce of castor oil is given 48 hours before operation.

A bowel wash is given the night before and morning of operation.

No vaginal douches are given as these make the vagina 'soggy' and friable, and increase the amount of hæmorrhage during operation.

Operation—Instruments used

The ordinary standard set of gynæcological instruments is used with the addition of the following :—

(1) *Scissors*.—Irwin Moore's cleft-palate, seven inches long, curved on flat, one pair fully curved, one pair slightly curved. The cutting blades are one-and-a-quarter inches in length. I have had the points slightly modified to correspond to a very blunt pair of Mayo's scissors.

(2) *Dissecting forceps*.—One pair of long tonsil forceps with rat teeth. One pair of long tonsil forceps with the teeth ground away.

(3) Luc's angular nasal forceps for the assistant to use when swabbing.

(4) *Needle holder*.—Bozeman's.

(5) *Needles*.—Mayo's nos. 12 and 18.

(6) *Sutures and ligatures*.—20-day catgut, nos. 0000, 00 and 1.

Operation

The patient is shaved in the ward, and prepared on the table by thorough cleaning of the vagina, vulva and buttocks, with cotton-wool dipped in ether soap, followed by douching with sterile water, drying and painting with methylated spirits.

Access to fistula

It is of great importance that adequate access be provided. The use of Schuchardt's incision is of the greatest value, and, if properly carried out, converts the vagina into a wide funnel with the apex at the top. The incision can be made on the right, left or both sides. I have never had occasion to make more than a single incision and usually on the left side.

Schuchardt's incision and author's modification

In several cases, owing to excessive cicatrization of the vagina, it has been necessary to 'borrow' tissue from the skin of the buttocks. In order to do this, I have modified the original Schuchardt's incision. Figure 1 shows the Schuchardt's incision indicated by a thick black line, the modification by dotted lines. This incision should be made as follows:—

(1) The posterior commissure is placed under tension by picking up the left labium at the point marked 'A' in figure 1 with a pair of tissue forceps, and retracting outwards and forwards. The operator places the left index finger in the vagina and tenses the fourchette forwards and, at the same time, presses the rectum backwards and to the right with the tip of the finger. The incision in the fourchette and perineum is made by cutting outwards and backwards. The anterior end of the incision extends about half an inch inside the vagina, the posterior end midway between the anus and tuber ischium.

The incision is deepened until the levator ani is seen.

The vaginal incision is then extended upwards along the junction of the left posterior lateral wall of the vagina as high as is desired, and only including the vaginal mucous membrane.

Three important points must be noted—

(a) to keep tension on the vaginal walls when cutting;

(b) to press the rectum backwards and to the right with the left index finger; and

(c) to cut outwards and backwards.

The anterior fibres of the levator ani may be incised if additional space is required.

In cases of great contraction of the vagina requiring a plastic operation, I have modified the original incision as follows:—

After cutting through the posterior commissure and proceeding downwards for about half to three-quarter of an inch (to 'X', figure 1) the incision is curved outwards and to the left for one-and-a-half inches (figure 1, 'B', dotted line). The incision is then proceeded with as described above.

After closure of the fistula, an estimated amount of new tissue required to form an adequate vaginal lumen is made, and a flap of suitable size made by extending the original incision from 'X' (the flap is shown in dotted lines, figure 1). By freely undercutting, a mobile flap can be formed and swung into the vagina, the apex of which can be approximated to as high as the cervix.

The results of this manœuvre have been most gratifying.

Fundamental principles required for successful operation

(1) Free exposure is essential. This is obtained by Schuchardt's incision.

(2) The bladder must be thoroughly mobilized. By thorough mobilization, I mean that when the bladder has been separated from the

Fig. 1.

vagina, it can easily be pulled into the vagina and approximation of its walls during suture be made *without tension*.

(3) The same remarks apply to cases in which the urethra is involved. The anterior and lateral walls must be freed from the vaginal wall, until the urethra can be approximated to the bladder *without any tension whatsoever*.

(4) Accurate suturing.

In addition, infiltration of the entire area with adrenaline solution or adrenaline and novocaine will considerably reduce the amount of hæmorrhage.

Method of closing simple fistulæ

The edges of a fistula should never be excised. (Excision is recommended in most textbooks.) As a result of excision, the bladder mucous membrane retracts and post-operative hæmorrhage results, very often of a serious nature and always troublesome to control.

The first step is the separation of the bladder from the vaginal wall, followed by mobilization of the bladder. An incision is made with a pointed scalpel, one-sixteenth inch from the edge of the fistula, through the vaginal wall and down to the bladder. Upper and lower incisions of suitable length are made at the same time (figure 2, 'BB'). The remainder of the mobilization of the bladder is carried out by means

Fig. 2.

of the Irwin Moore's curved scissors and tonsil forceps. The edge of the fistula is held by the forceps and the bladder wall identified by means of cutting and blunt dissection with the scissors. Once this identification is made, the vaginal wall is easily stripped from the bladder by means of the scissors, and free mobility of the bladder is obtained.

Suture and closure of the fistula

Two continuous sutures are inserted of 0000 20-day catgut on a small Mayo's needle (no. 12 or 18).

The first suture is considered the most important.

At the edge of the fistula and in the bladder muscle, a certain amount of fibrous tissue is present, i.e., there is a ring of fibrous tissue just external to the fistula. This fibrous tissue is formed as a result of inflammation and repair. By inserting the needle deep into the bladder on the left side, and working the point of the needle mesially towards the fistula, one can appreciate that the needle penetrates and picks up a tissue that is strong and tough and in marked contrast to the bladder muscle. The point of the needle is made to emerge slightly external to the cut edge of the vagina. The reverse process is carried out on the right side. Tightening of this suture inverts the edges of the fistula.

A diagram of a section of figure 2 at 'AA' illustrates these points.

I consider the picking up of this strong fibrous tissue a most important point in technique and aid to success.

This continuous suture closes the fistula.

The second suture is a continuous Lembert's with 0000 or 00 20-day catgut, which passes through the bladder muscle and covers over the first suture.

The vagina is closed with a continuous no. 1 20-day catgut suture.

Method of closing complicated fistulae

These fistulae vary enormously in size, in the amount of tissue destroyed and in the degree of cicatrization of the vagina. The chief difficulties are:—

(1) to provide sufficient mobility to enable suture to be performed;

(2) to provide sphincteric control; and

(3) to attach the remaining portion of the urethra to the bladder.

Two outstanding features in the operations performed have been—

(1) the inability to recognize anything that may have been regarded as a sphincter of the bladder, and

Fig. 3.—Sectional diagram at 'AA', figure 2, to show method of inserting the first stitch.

(2) the extraordinary manner in which sphincteric control has been obtained, when a fistula has been closed and attached to the remains of the urethra. It would appear that, providing the aperture is closed to a sufficient degree, sphincteric control rapidly becomes established. I can give no explanation of this peculiar fact.

Provision of mobilization

The preliminary steps are as for simple fistulæ. It will be found, however, that free mobilization is not so simple, as the bladder adjacent to the fistula is frequently adherent to the posterior surface of the symphysis pubis and to the rami of the pubes by fibrous tissue—often in the form of bands. These can be palpated by the finger and divided by scissors. By palpation and scissors cutting, all fibrous adhesions are freed until the bladder is completely free.

Treatment of urethra

The urethra is mobilized by making a vertical incision over the upper three-quarters of its length and reflecting the vaginal wall anteriorly and laterally. It is invariably contracted, and, after it is freed, an extra one-third of its length can be obtained without any increased tension.

The tissue lying between the posterior wall of the urethra and the fistula should, when necessary, be widely undercut and freed. It can then be used as a new upper part of the urethra, or the undercutting allows of easy approximation of urethra to bladder.

Suture of bladder

If possible, two vertical 0000 catgut sutures are used. In very large fistulæ it is sometimes necessary to suture transversely.

The first suture is inserted from above, downwards, and when the fistula is nearly closed, a no. 8 self-retaining rubber catheter is inserted through the urethra into the bladder. The first suture is then completed and the bladder is comfortably tightened over the rubber catheter at the site of the new internal os.

The urethra is then attached to the bladder by a transverse 0000 continuous catgut suture, followed by a second 0000 suture.

If there is excessive stenosis of the vagina, a flap is designed, turned in from the buttock and sutured in place.

Post-operative treatment

(1) In every case a self-retaining catheter is left in the bladder—usually for ten days—but longer, if considered necessary. The catheter is connected to a drainage bottle.

(2) Bladder washouts twice daily.

(3) From the third day, a catheter vaginal douche is given daily. After douching, the vagina is dried with cotton-wool on a probe.

If the discharge is unhealthy, hydrogen peroxide is used before the douche.

(4) Diet—fluids until fifth day.

(5) Bowels opened on the fourth day, with liquid paraffin and olive-oil enemata daily and mild aperients.

(6) From the tenth day (average) the bladder catheter is removed for an interval which is increased daily. Usually by the fifteenth day it is entirely omitted.

Summary

(1) A description is given of the operative treatment adopted in thirty-three cases of vesico- and vesico-urethro-vaginal fistulæ by the vaginal route.

(2) A modification of Schuchardt's incision is described for use when plastic operations on the vagina are necessary.

(3) A method is described of inserting the first stitch, when closing the bladder fistula.

Cases 4, 13, 18 and 25 were operated on by my assistant, Dr. J. E. R. Heppolette, by the technique described, and I have to thank him for allowing me to include them in this series.

I have to thank Sister Bamford and the nursing staff of the Lady Willingdon Hospital for the great interest they have taken in the post-operative treatment.

Case and operation details

- Case 1.—Hussaina, aged 28, admitted on 6th October, 1930. Dead child born nine months ago, since then had dribbling of urine per vaginam.
- Operation.—Fistula admitting two fingers easily, involved upper part of urethra and base of bladder. Free mobilization of bladder and urethra difficult owing to adhesions between bladder and urethra. Difficult face of symphysis. Bladder closed with posterior surface of symphysis. Bladder sewn to 0000 vertical Lembert's catgut suture. Urethra exposed and transversed. Difficult mobilization as bladder was firmly adherent to posterior surface of symphysis. Vaginal flaps closed with 00 catgut. Result, cured.
- Case 2.—Aisha Bibi, admitted 6th June, 1931. Notes incomplete. Repaired vaginally. Result, not cured.
- Case 3.—Ahmadi, admitted on 21st February, 1931. Notes incomplete. Repaired vaginally. Result, cured.
- Case 4.—Has had dribbling of urine per vaginam since birth of last child three months ago. Two previous children born without complications. Notes incomplete. Operation vaginally for urethro-vaginal fistula. Result, cured.
- Case 5.—Admitted on 9th February, 1931. Notes incomplete. Repaired vaginally. Result, not cured.
- Case 6.—Two para. Two months ago delivered of a child, since then dribbling of urine. Vesico-vaginal fistula (V-V F) admitting two fingers tightly. Upper one-third of urethra destroyed. Bladder freed by scissors dissection, mucous membrane over urethra incised vertically and urethra freely exposed. Bladder sewn transversely and urethra freed. Flap of urethra joined by 00 30-day catgut. Upper end of labia minora laterally, undercutting, and sliding flaps turned down from cervix. Lateral flaps freed. Flap across. Left hospital with quarter-inch fistula remaining. To return later. Re-admitted 21st April. A fistula of urethra (urethro-vaginal fistula). Urethra exposed by vertical incision. Bladder mobilized. Closed by vertical 0000 catgut suture. Vaginal mucous membrane by 00 catgut. Result, cured. Left hospital with full control and no leakage.
- Case 7.—Admitted on 29th August, 1931. Three normal pregnancies. Last, one year ago. Dribbling of urine per vaginam for one year. Fistula in anterior fornix. Large amount of scar tissue. Notes incomplete. Operation vaginally. Result, cured.
- Case 8.—Aged 20. One child one year ago, since birth of which she has been suffering from incontinence of urine and faeces. Has also right and left tubo-ovarian abscesses. The vagina is contracted by a transverse fibrous ridge on the posterior wall. The first finger can be passed through with difficulty and passes into a large recto-vaginal fistula.
- 27th January, 1932. Right and left tubo-ovarian abscesses removed and pelvis drained. Also recto-vaginal fistula closed. Schuchardt's incision cutting through the transverse fibrous ridge. Fistula admitted two fingers. Closed with two Lembert's 0000 suture. 10th February. Vesico-vaginal fistula. Admitted little finger. Upper part of urethra completely destroyed. Bladder mobilized. Rubber catheter inserted. Bladder closed with Lembert's suture. Upper part of urethra exposed, stitched to bladder transversely with interrupted sutures. On discharge there is a small opening in the urethra admitting a very fine probe, which will probably close. Bladder control good, and only very slight dribbling from fistula. To return for second operation in one month if fistula does not close and there is any inconvenience. Patient did not return. Assumed cured.
- Case 9.—Admitted on 22nd November, 1932. Complains of passing urine continuously for eight months, since birth of a dead baby removed by instruments. Had two previous normal labours.
- Operation.—29th November. Fistula 1 cm. wide. Only the lower one-third of urethra remaining. Fistula involves base of bladder and high up vaginal wall on left side. Bound down firmly to posterior surface of symphysis. Free dissection made—bladder sutured to urethra. Prognosis doubtful. Convalescence uneventful. 14th December. Wound healed perfectly. No leakage except on coughing, bending and walking. To return in two months for further operation.
- Re-admitted on 13th February, 1933. Wound has healed quite satisfactorily. No sphincter control. Cervix is fixed on left side and cannot be pulled down. Urethra although only one inch long is functioning. There is a small cystocele present.
- Operation.—21st February. Wide separation of bladder away from scar and double plication near junction of urethra and bladder. Catheter for ten days. Result.—11th March. Has now complete control of bladder.
- Case 10.—Aged 40. Admitted on 14th December, 1933. Complains of frequency and severe pain during micturition. Symptoms started one year ago, when she went into the jungle to pass urine. States she fell down on to a cotton plant and injured her perineum.
- Examination.—Patient is extremely weak and emaciated. Temperature 99°F., pulse 100. The vagina is filled by a calculus which cannot be removed.
- Operation.—19th December. The vagina contains a phosphatic stone of the size of a hen's egg. There is a narrow pedicle anteriorly which passes through the vaginal wall into the bladder. On sounding the bladder a stone is felt. Suprapubic opening made into bladder. The bladder wall is three-fourths inch thick due to chronic inflammation. A phosphatic stone removed, the size of a pear. Two ounces of pus evacuated. Bladder washed and drained. The pedicle was then easily removed. It was found that the stone was a piece of stick encrusted with phosphates. The stick was three inches long and one-fourth inch thick. Is called in the vernacular 'an abortion stick'. An attempt had evidently been made to produce abortion but the stick instead of passing into the uterus, had been pushed into the bladder. A V-V F had formed and phosphatic stones formed around the free ends and phosphatic fistula admitted a thick probe. Closed on 23rd January, 1934, by usual technique. Discharged on 15th February. Has greatly improved in health and weight. No complaints. Result, cured.

Case 11.—Aged 30 years. After birth of a dead child two years ago she had fever for four months. She then found that mæces and urine were passed per vaginam.

Examination.—Vagina is cicatrized and admits one-and-a-half fingers. There is a recto-vaginal fistula just above the sphincter ani which admits two-and-a-half fingers. A vesico-vaginal fistula high up admits the little finger easily.

Operation.—22nd March, 1933. Left Schuchardt's incision. Recto-vaginal fistula closed. Convalescence uneventful. To return in six months for operation on V-V F.

Re-admitted on 2nd April, 1934. A remarkable improvement is present. The vaginal tissues are soft and pliable and there is no evidence of fibrous tissue or old operation scars, except a very fine line at site of Schuchardt's incision.

Operation.—11th April. Right Schuchardt's incision. The V-V F admitting easily the little finger is high up and involves the urethral wall, the left lateral part being completely destroyed. Urethra freely exposed and a new left lateral wall fashioned from the vagina. Closed with two vertical Lembert's suture 0000 catgut. Good exposure was difficult and prognosis doubtful as a perfect loose fit was not possible. Catheter left in for 16 days. Result, control perfect.

N.B.—The difference between prognosis and result.

Case 12.—Aged 16. Admitted on 15th March, 1934. Complained of constant dribbling of urine for one year since the birth of a child.

Examination.—A fistula at the junction of bladder and urethra admits the little finger. Slight cystocele also present.

Operation.—20th March. Urethra and bladder freely exposed. Fistula sewn transversely with Lembert's suture 0000 catgut, and then vertically with 0000 Lembert's suture. (Bladder was plicated.) Anterior colporrhaphy. Result, cured. Discharged 21 days after operation.

Case 13.—Aged 35. Live baby born after long labour four months ago.

Operation.—9th July, 1934. Fistula involving the upper end of the urethra and the base of the bladder admits little finger. Mobilization difficult. Re-operated on 23rd July, and a small remaining fistula closed. Result, cured.

Case 14.—Aged 27. Dribbling of urine for four months since birth of child. Vagina extensively cicatrized and admits one finger fairly easily.

Operation.—5th October, 1934. Fistula at base of bladder admitted little finger. Left Schuchardt's incision. Free mobilization; sutured with 0000 Lembert's. Vagina closed with no. 1 catgut. Self-retaining catheter 12 days. Result, perfect control.

Returned 25th October, 1935. Nine months' pregnant. Caesarean section performed. Live male child. The vagina was normal, admitted two fingers easily and there was no evidence of previous cicatrization and operation.

Case 15.—Aged 25. Complained of incontinence of urine for two years. Fistula one-third of an inch in diameter at junction of bladder and urethra. Free mobilization and closure by two 0000 transverse Lembert's suture. Result, cured.

Case 16.—Aged 35. Admitted on 25th May, 1935. Complained of passage of urine per vaginam. Four months ago was operated on for stone in the bladder and afterwards developed incontinence. Fistula admits two fingers and involves the upper one-third of the urethra and base of bladder. No cicatrization of the vagina.

Operation.—12th June. Free exposure of bladder and urethra which was one-and-a-half inches long. Sutured with double Lembert's 0000 and 00. Bladder plicated. Vagina closed with mattress and continuous sutures. Result, perfect control.

Case 17.—Aged 25. Incontinence of urine after dead child born two years ago.

Operation.—30th October, 1934. Fistula admits little finger and is situated at junction of bladder and urethra. Free exposure of upper part of urethra and

bladder. Sutured with two 0000 vertical Lembert's suture. Result, cured.

Case 18.—Three para. Aged 23. Complained of dribbling of urine through vagina following birth of a dead female child four months ago. Is emaciated and weak.

Operation.—1st July, 1935. Fistula admits little finger and is close to cervix. Closed with double Lembert's. Leaked about seventh day. Discharged with pin-head opening which would heal spontaneously. Advised to report if not healed in three months.

Case 19.—Aged 18. Two para. After four days' labour gave birth to a dead child one year ago. Since then urine has been dribbling from the vagina. Pelvic measurements—8½, 10½ and 7½ inches. Was probably an occipito-posterior.

Operation.—20th December, 1935. V-V F size of thumb nail at vesico-cervical angle and on left lateral side. Good mobilization of the bladder obtained. Fistula very adherent to cervix. Closed by double 00 catgut Lembert's suture. Vagina closed with no. 1 catgut. Result, cured.

Case 20.—Two para. One year ago gave birth to a stillborn child, since then has had incontinence.

Operation.—20th December, 1935. A V-V F admitting one finger easily at the base of bladder. Adherent to cervix and on left lateral side. Free mobilization, and sutured with double 00 Lembert's suture. Anterior colporrhaphy. Result, cured.

Case 21.—Aged 18. One para. Complained of incontinence of urine for seven months since birth of a dead child. Was five days in labour and membranes ruptured three days before birth.

Operation.—15th April, 1936. Urethra one-and-a-half inches long and displaced to left. Upper end absent. A V-V F and U-V F admitting one finger are present. Cervix not seen, but a fine probe passes posteriorly to the cervix into what was formerly the vault of the vagina but is now a dense mass of fibrous tissue. Left Schuchardt's incision. Mobilization of bladder difficult owing to fibrosis. Urethra mobilized and sutured to bladder by two transverse 00 Lembert's suture. Insufficient vaginal wall remaining to form effective covering. Prognosis bad.

Result.—Leakage on sixth day after operation, which gradually diminished. Fourteen days after small fistula present admitting thick probe. Was continent at night and during the day except when frightened or when coughing.

Commentary.—Has partial control. Requires further operation in six months' time if not spontaneously cured.

Case 22.—Aged 22. One para. Dribbling of urine after birth of dead child two months ago. Labour lasted three days. General condition good. Is strong and healthy. Pelvic measurements—I S 9 inches, I C 10 inches, E C 7 inches, T at O 2½ inches.

Operation.—5th May, 1936. Uterus R V and mobile. Fistula quarter inch in diameter at junction of bladder and urethra which was displaced and bound down to the left side. Distal to the fistula was a constriction due to cicatrization of posterior vaginal wall, and producing an hour-glass contraction of vagina. Cervix not seen and is evidently above constriction, through which a finger will not pass. Modified left Schuchardt's incision, dividing constriction and exposing cervix. Bladder mobilized and upper part of urethra exposed. All adhesions binding fistula to the left divided by scissors cutting. Fistula and urethra closed by vertical double 00 Lembert's suture. A long flap was made by extending Schuchardt's incision outwards and extensively undercutting. The distal end was then sutured to the area on posterior wall of vagina which was deficient due to the constriction being divided.

Result.—Complete control. Vagina admits one-and-a-half fingers to vault. Cervix easily seen. To return in three months for plastic operation on vulva.

Case 23.—Aged 24. Two para. Complained of dribbling of urine for one year immediately following breach presentation. Had been in labour 40 hours, after

which a *dai* extracted the *fœtus*. Measurements—*I S* 8½ inches, *I C* 9½ inches, *E C* 6 inches, *T* at *O* 2 inches.

Operation.—29th May, 1936. Uterus *R V* and to right. Bladder mucous membrane prolapsed into vagina. Fistula admits two fingers loosely and involves upper part of urethra and base of bladder. Adherent to cervix. Left Schuchardt's incision. Bladder and urethra freely mobilized. Bladder sutured vertically with 0000 catgut as far as urethra. Urethra joined to bladder by transverse 0000 Lembert's suture. Bladder and urethra reinforced by one vertical 0000 Lembert's suture. A fibrous constriction on posterior wall one inch from cervix was divided and the tissue replaced by swinging the mesial flap upwards.

Although the fistula appeared to be inoperable, mobilization was fairly easy and suture without tension was obtained. Doubtful prognosis and almost certain to have no control.

Result.—Fifteen days after operation, wound healed except one small granulating area. Catheter kept in for 19 days, after which slight dribbling, then complete control.

Case 24.—Aged 35. Seven para. Complaints of dribbling from vagina. Duration six months. Gave birth to a stillborn child by instrumental delivery after 39 hours' labour. Measurements—*S*½, 9, 6 and 2½ inches.

Operation.—29th September, 1936. Left Schuchardt's incision. The cervix was fissured due to old lacerations. Is mobile in spite of abundant scar tissue. Small cystocele present. There are two fistulæ—the right one-eighth inch in diameter to the right lateral side and the left quarter inch in diameter to the left lateral side. Exposure of the right fistula difficult and entailed very wide lateral dissection. The right sutured with 2×00 catgut vertically. The left sutured with 2×00 catgut transversely. Result, cured.

Case 25.—Aged 22. One para. Complaints of dribbling of urine for two months following difficult and prolonged labour. The trouble started after the third day of delivery. Has a large fistula admitting two fingers just behind the symphysis pubis. Bladder well prolapsed. Mobilization easy. Sutured by double 0000 Lembert's suture, transversely. Result, cured.

Case 26.—Aged 32. Two para, both stillborn. Six years ago was delivered of a dead child. Fifteen hours in second stage. Forceps applied. Retention of urine for fifteen days after labour, then dribbling of urine. Twenty-five days afterwards was operated on vaginally unsuccessfully. Pelvic measurements—7½, 8½, 7½ and 3 inches. There was a small fistula admitting a thick probe at junction of urethra and bladder. Scar tissue + +.

Operation.—16th September, 1936. Cervix high and fixed by scar tissue. Large rectocele. Mobilization difficult owing to cervix being fixed by scar tissue. Fistula also adherent to rami of pubes. Fistula sutured 2×00 catgut. Transverse suture. Result, cured.

Case 27.—Aged 25. Four para—first dead, second alive, third and fourth born dead. Complaints of watery discharge per vaginam for one month. Dribbling of urine commenced ten days after delivery one-and-a-half months ago. Labour pains began at 7 p.m. Next day at 12 noon the head was born. The pains then ceased and there was no advance until 6 p.m., when four *dais* pulled out the dead child. Dribbling of urine commenced after ten days. Pelvic measurements—7½, 8½, 6½ and 3 inches.

Operation.—16th September, 1936. Fistula as large as little finger at junction of bladder and urethra. Bound down to the right side of descending ramus of pubis. Easily mobilized. Sutured with 2×00 catgut. Bladder neck plicated with three interrupted no. 1 sutures. Result, cured.

Case 28.—Aged 26. Dead baby born in October 1935 after four days' labour. Three weeks later she found that urine was dribbling from the vagina. Pelvic measurements—8, 8½ and 5½ inches. Outlet 1½ inches. Vaginal examination showed a recto-vaginal fistula. The urethra is completely destroyed and absent. Scar tissue + +.

Operation.—29th September, 1936, for recto-vaginal fistula and plastic for stenosed vagina. There was a transverse posterior bar of fibrous tissue two inches from the vaginal outlet, contracting the vagina to one finger. Recto-vaginal fistula, size of one shilling, on the left side bound to the ramus of the pubis by fibrous tissue. Fistula extends to the anal canal. Free mobilization and suture by 2×00 catgut. Author's modification of Schuchardt's incision for flap to insert in vagina.

11th October. The external wound had healed. The flap inside the vagina is united except for a small raw area near front part.

30th October. Operation for vesico-vaginal fistula. The urethra was completely absent. Fistula mobilized and a tube from the bladder formed for the new urethra. Tissues split and undercut under the symphysis at old urethral site. This formed a bed for urethra. The urethra was sutured in original site and the undercut flaps sutured over.

25th November. The urethra has retracted to half its length but there is complete control of micturition. Discharged cured.

Case 29.—Aged 14. One para. Six months ago dead baby removed with instruments by three *dais*, following 72 hours' labour. Second stage 48 hours. Now complains of incontinence of urine.

Operation.—23rd October, 1936. The fistula is urethral and is high up behind a horseshoe-shaped fold which is the vault of the vagina. Scar tissue + +. No evidence of cervix or urethra. Left Schuchardt's incision. Urethra and bladder mobilized. Poor exposure due to difficulty in working under narrow pubic angle. Peritoneal cavity accidentally opened—re-sutured. Only possible to insert one transverse suture. Prognosis, bad.

Result.—On 24th November, a pin-hole fistula remains which will possibly heal up itself. If not, to return in two months. There is considerable sphincter control and only slight dribbling.

18th December. Returned for examination. Fistula has healed. Now has complete control. Result, cured.

Case 30.—Aged 29. Four para. History of last labour.—Admitted to hospital after being 70 hours in labour. Membranes ruptured 63 hours previously. Attended by four *dais*. Oedematous and contused labia and vagina. Bladder distended. Vaginal discharge foul and stinking. No *fœtal* heart sounds. Albumin in urine + + +. Temperature 100°F. Pulse 110. Face presentation. Craniotomy and episiotomy performed. Vaginal laceration stitched. Normal puerperium. Ten days later complained of dribbling of urine from vagina. Measurements 8½, 9½, 7½ and 3 inches.

Operation.—25th October, 1936, for vesico-vaginal fistula. Fistula is to the left and two-and-a-half inches from the urethral orifice. Mobilized easily but found to be adherent behind the left side of symphysis. When freely mobilized was one inch in diameter. Sutured by two 0000 Lembert's suture. Result, cured.

Case 31. Aged 30. Eight para. Last eight months ago. Pelvic measurements—8½, 10, 6½ and 3 inches. Complaints of dribbling of urine per vaginam. Duration eight months. Last labour was 80 hours. Was delivered of a dead child. Spleen enlarged six fingers below the costal margin. General condition poor.

Operation.—8th December, 1936. Fistula ½-inch in diameter at junction of vagina and cervix. Cystocele present. Mobilization easy. Fistula closed by two vertical 00 Lembert's suture. Anterior colporrhaphy. Prognosis good as operation was extremely easy and tissues in good condition.

Post-operative condition.—Complete anuria for 48 hours. On the third day temperature 100°F., pulse 140. Blood-stained urine, three cuneces, passed. Diagnosed as blackwater fever. Treated as such. Died on the fifth day after operation. Urine passed was never more than three ounces per day.

Case 32.—Aged 25. Married 15 years. One para. Full-term dead baby four months ago, delivered with (Continued at foot of next page)

TREATMENT OF MALARIA IN CHILDREN WITH ATEBRIN-MUSONATE*

By R. K. DE, L.M.F., D.T.M.

Assistant Medical Officer, Talap Tea Estate, Talap, Assam

Introduction

THE difficulty in giving quinine by mouth due to its bitterness and uncertainty of the amount retained when given are the most important drawbacks experienced in treating children with malaria, especially in tea-garden hospitals at the height of the malarial season, when one or two compounders have to administer quinine orally to 40 to 50 children or more three or four times a day. Atebrin by mouth is almost equally difficult. In view of the above facts and encouraged by the good results reported by many workers of the two-injection method of treatment with atebrin-musonate, it was decided to try this method of treatment in children in tea-garden practice. If such a method of 'rapid treatment' would be effective and practicable and without any risk, it would certainly be of great advantage to tea gardens from the economic point of view, as this would do away with the present hospitalization period of seven to ten days for the mothers and their

*Being a paper read at a meeting of the Assam Frontier and Budla Beta Medical Society held on 16th January, 1937.

(Continued from previous page)

forceps, after 20 hours' labour. Urine commenced dribbling per vaginam on the following day. Patient has osteomalacia. Thighs flexed on trunk.

Operation.—10th November, 1936. Urethra was displaced to the right and opened at the junction of the anterior and middle third of the labium. Large fistula one inch in diameter involving upper part of urethra and bladder. Bladder prolapsed and adherent to the symphysis and both rami. Mobilization difficult. Urethra freed and correctly sited. Fistula closed and sutured to urethra. Prognosis hopeless.

Seen again on 18th January, 1937. Has control over micturition. Urine passed three or four times daily.

N.B.—The difference between prognosis and result.

Case 33.—Aged 32. Gave birth to dead child ten years ago, after four days' labour. Attended by five dais. Urine passed per vaginam two days after delivery. Has had three previous operations.

Operation.—4th December, 1936. Vagina is cone-shaped and half-inch in diameter at the apex. Cervix not seen. Extensive fibrosis of vault of vagina. Upper three-quarters of urethra absent. Large fistula one inch in diameter, in the base of the bladder. Left Schuchardt's incision. Mobilization difficult owing to scar tissue. Urethra freely mobilized. Closure by only one suture possible. Bladder and urethra covered by borrowing flaps from the lateral wall of the vagina.

Prognosis not good owing to necessity of suturing through fibrous tissue and imperfect mobilization.

23rd December. Urine good. Small fistula admitting fine probe remaining. Second operation will certainly close it. Control good. Result, partially cured.

Mein, W. A. (1936). *Brit. Med. Journ.*, Vol. I, p 1207.

children and render necessary a period of not more than two or three days; thus loss of labour to the management, especially in the plucking season, would be saved.

The experiment was carried out in a tea garden in Upper Assam from 14th August, 1936, to 20th September, 1936, and all children with uncomplicated malaria from 6 months to 6 years of age (only three children were above 4 years) were treated with atebrin injections. The total number of cases was 50. Table 1 shows their age grouping, the ages being recorded from the garden birth register, with four exceptions. Two injections were given—one every 24 hours (only two cases were given a third injection)—the dose being 0.1 gm. of 'injectable atebrin' dissolved in 3 c.cm. of distilled water and the injection given into the buttock. No subsequent oral treatment was given. Before beginning treatment, the diagnosis was confirmed by blood examination. Daily thick and thin films were taken from each case and this was continued until the blood was negative for three consecutive days; a blood slide was recorded as negative when no parasite could be found by searching the whole thick film. The physical development of children was noted. The splenic enlargements were roughly measured on the first and fifteenth days. Hæmoglobin was estimated on the first, seventh and fifteenth days by Tallqvist's scale.

Showing age grouping

6 months to 1 year	12
1 year to 2 years	16
2 years to 3 years	10
3 years to 4 years	9
4 years to 6 years	3
TOTAL				50

Observations

Temperature and other symptoms.—The effect on the temperature was striking. In most of the cases this came down within 24 hours, i.e., before the second injection. The average time for the temperature to settle down to normal was 1.33 days after beginning treatment.

Within a few days of treatment, parasites reappeared in the blood in six cases without any fever and disappeared spontaneously. In nine cases fever returned—four without and five with parasites. Amongst the latter five, only in two cases, the fever being high, a third injection was given, and this without any ill effect in one case on the sixth day and in the other on the eighth day—the ages being 4 years and 14 months, respectively.

Nine cases were gravely ill on admission—two with hyperpyrexia, five with convulsions, one

with diarrhoea and one with dyspnoea. In all these cases, except one with convulsions, the grave symptoms were rapidly controlled after one injection. The excepted case was a very bad one admitted with fever, bilious vomiting and convulsions, a heavy malignant tertian infection, age 1½ years. The child died 19 hours after admission, one injection having been given. Convulsions continued during the whole of this period.

Parasites

The parasites disappeared from the peripheral blood on the average in 2.04 days after beginning treatment.

Subtertian parasites disappeared earlier than the benign tertian and in mixed infection subtertian parasites disappeared first in all except two cases in which they disappeared at the same time. This finding is in conformity with the finding of Flack, Majumdar and Goldsmith (1936). Parasitic counts were not done in this series. In one case, however, parasites appeared to be definitely increased after the first injection. This phenomenon has also been recorded by Carman and Cormack (1936). In four cases crescents were found on admission and these persisted after treatment. In 10 cases crescents appeared a few days after treatment and in one of these even half-grown crescents were encountered two to three days before the appearance of full-grown crescents.

TABLE III

Showing persistence of parasites in days after beginning treatment

Malignant tertian	..	1.89
Benign tertian	..	2.15
Both	..	2.04

Spleen

On admission, 45 cases (excluding the child that died) had enlarged spleens and by rough measurement reduction in size was noticed in 22 cases.

Physique

The physical development of four children was under average. In these no modification of dose was made and no definite sign of intolerance was noticed.

Toxicity

Hecht (1933) has shown experimentally that 'atebrin is a drug of mild and uncharacteristic toxic properties.....the central nervous system and especially the cerebrum are stimulated by lethal doses'. Col. Dunn (1936) reports that during the 1934-35 malaria epidemic in Ceylon where atebrin-musonate was extensively used by Briercliffe and others, there occurred in a certain percentage of cases toxic manifestations such as collapse, convulsions and even death a few minutes to a few hours after injection and that children are specially liable to such collapse and convulsions.

In this series no immediate fatality occurred. Convulsions in five cases and restlessness with vomiting in one case were noticed after injection. The details are given below:—

Case 1.—Girl, aged 1½ years, physique under average, M. T. heavy, Hb. 45 per cent, was admitted with fever. On 1st September, 1936, first injection was given; there were convulsions for a few minutes about three hours after. Next day second injection was given; recovery was uneventful. On 26th September, 1936, admitted again with febrile recurrence, B. T. moderate (a reinfection); a single injection was given; recovery was uneventful.

Case 2.—Boy, aged 6 months, physique good, M. T. heavy, Hb. 60 per cent, was admitted with fever. On 1st September, 1936, first injection was given; shortly after this, convulsions occurred for a few minutes. Next day second injection was given; recovery was uneventful. On 2nd October, 1936, admitted again with febrile recurrence, B. T. moderate (a reinfection); a single injection was given and shortly after this convulsions occurred for a few minutes.

Case 3.—Boy, aged 3½ years, physique good, M. T. heavy, Hb. 70 per cent, was admitted with fever. On 18th September, 1936, first injection was given; convulsions occurred for a few minutes about an hour after. Next day second injection was given; recovery was uneventful.

Case 4.—Girl, aged 1½ years, physique good, B. T. moderate, Hb. 65 per cent, admitted with fever. On 18th September, 1936, first injection was given and no untoward symptom followed. Next day second injection was given; convulsions occurred for a few minutes about half an hour after.

Case 5.—Boy, aged 2½ years, physique average, M. T. and B. T. heavy, Hb. 40 per cent, was admitted with fever and diarrhoea. On 22nd September, 1936, first injection was given; there were convulsions for a few minutes about two hours after. Next day second injection was given, recovery was uneventful. On 20th October, 1936, admitted again with febrile recurrence, B. T. moderate (a relapse or a reinfection); a single injection was given; recovery was uneventful.

Case 6.—Girl, aged 3½ years, physique average, M. T. and B. T. heavy, Hb. 65 per cent, was admitted with fever and history of convulsions. On 8th October, 1936, first injection was given; no untoward symptom followed. Next day second injection was given; restlessness with vomiting occurred about four hours after; slept under bromide.

In cases 1, 3 and 5, we were not inclined to hold atebrin responsible for the convulsions, as there was no such symptom following the second injection nor did such symptom follow the injection during the febrile recurrence in cases

1 and 5. Such convulsions were most probably due to the heavy malarial infection which these cases had. We have seen similar symptoms in malarial cases after quinine injection as well, but we were not disposed to hold quinine responsible for those.

Case 2 is interesting because of the fact that convulsions also occurred after the injection was given for the febrile recurrence. Is it because of 'specific sensitivity' as hinted at in the editorial in the *Indian Medical Gazette* of December 1935?

Only in cases 4 and 6 could the symptoms possibly be attributed to atebtrin. They apparently looked well and had no temperature nor any other symptom at the time of second injection.

Another case is worth mentioning and may be of interest to compare with one in Col. Dunn's (1936) records. This case of Dr. Fernando's died two months after atebtrin injection and post-mortem examination revealed the case to be one of atebtrin poisoning. The details of my case are as follows:—

Boy, aged 10 months, physique good, M. T. moderate, Hb. 65 per cent, was admitted with fever on 20th August, 1936. Two usual injections on consecutive days were given. Recovery was uneventful. No recurrence of fever or parasites was noted afterwards. On 21st October, 1936, i.e., two months after, the case was re-admitted to hospital with a sloughing ulcer on perineum of about a week's duration. There was neither fever nor any other constitutional disturbance. Next day the child suddenly died after a convulsive attack of a few minutes' duration. The cause of death seemed to me obscure. As post-mortem examination was neither done nor possible, no definite conclusion could be arrived at.

I mention this case because this sudden death, without any definite cause, happened to be in a case of this atebtrin series.

Slightly yellow discoloration of the skin was noticed in one case for two weeks.

Relapse.—An attempt was made to study relapses by following up the cases and by examining the blood every fortnight. It was possible to follow up these cases only for a month and a half. In a highly malarious area where risk of reinfection is great, it is difficult to distinguish relapses from reinfection and hence this observation has not been of much value. Thirty-four cases had parasitic relapse or reinfection (including some certain cases of reinfection).

Of these 34 cases, nine came under treatment with febrile recurrence (there might have been more such cases who were not brought to hospital or in whom fever passed unnoticed by the mothers). It may be noted here that these cases with febrile recurrences within the observation period of 45 days were treated again with a single injection of atebtrin 0.1 gm. with good clinical response.

Summary and conclusion

(1) Fifty children were treated with two consecutive daily doses of atebtrin by intramuscular injection.

(2) This treatment controlled the clinical symptoms rapidly and the effect on temperature was remarkable.

(3) The treatment freed the peripheral blood of malignant tertian infection earlier than benign tertian.

(4) The treatment did not destroy crescents nor did it prevent the formation of them.

(5) Post-treatment complications were unexpected and caused anxiety.

(6) There was no abscess formation and no inflammatory reaction in any case.

(7) The dose given seemed adequate for the average children of from 6 months to 6 years in tea gardens.

Taking all the above into consideration, although the number of cases is small, it is concluded provisionally that two injections of atebtrin can be regarded as an efficient course of treatment in acute malaria and its complications in children. The rapidity with which the temperature is controlled and the facility of administration of this method of treatment are really distinct advantages. The drawbacks are the toxic after-effects in some cases and its high price. The latter is largely overcome by the saving in hospital costs due to reduction in the treatment period, and will be more so if the relapse rate is also lessened by this method.

Acknowledgments

My grateful thanks are due to my chief, Dr. W. F. Whaley, for his help, encouragement and permission to read and publish this paper, and to Dr. H. L. Slaughter for helping me with a valuable reference. I am also indebted to my assistants, Messrs. N. C. Das, J. M. Ghosh and N. K. Acharjee, for their interest and sincere co-operation.

VITAMIN A, AS DETERMINED BY THE BLUE UNITS OF THE ANTIMONY TRICHLORIDE TEST, IN THE LIVERS OF MALNOURISHED CHILDREN

By LUCIUS NICHOLLS, M.D., B.C., B.A. (Cantab.)

THE livers used in this investigation were obtained from children of the indigent classes dying from various causes in the Colombo hospitals.

Carr and Price (1926) originally described a method of determining the amount of vitamin A by the use of antimony trichloride. A quantity of the liver, or other organ, to be tested was dried and extracted in a Soxhlet apparatus, and the test carried out with the extract. This is a tedious procedure when large numbers of tests are being done, and Moore (1930) modified it by dissolving the samples in 5 per cent caustic potash and shaking this up with a little alcohol, and extracting the fats and vitamin A by adding ether and shaking the mixture.

When working in a hot and damp climate special precautions must be taken to prevent the presence of moisture in the final extract.

The method which has been followed is that described by Davies (1933) with a few small modifications :—

Method

Five grammes of liver are weighed in a 50-c.cm. beaker and minced with scissors, 10 c.cm. of 5 per cent solution of KOH is added and the material is transferred to a 50-c.cm. conical flask. The mixture is digested in an oven at 100°C. until there is complete solution. It is poured into a 100-c.cm. graduated and stoppered funnel and 5 c.cm. of ethyl alcohol is added and well shaken, 50 c.cm. of ether is added and the shaking repeated. The layers are allowed to settle out and the aqueous layer is run off and discarded; 5 c.cm. of water is added and vigorously shaken with the other layer; the aqueous layer settles and is discarded; the washing to remove the KOH is completed by gentle agitation with 50 c.cm. of water (strong shaking produces an emulsion which will not readily settle into layers). The ether fraction is passed into a small flask containing anhydrous sodium sulphate and allowed to stand for a few minutes; this absorbs the water; the ether is filtered through a little more anhydrous sodium sulphate in a dried sintered glass funnel leading into 100-c.cm. wide-neck squat flask. The content of the flask is evaporated in a water bath, and, to prevent condensation of moisture, the flask is fitted with a cork through which two tubes pass—one leads to two wash bottles, the first containing sulphuric acid and the second caustic potash, and the other leads to a suction pump, thus only dried air enters the flask. The residue after evaporation should be a clear and transparent oil; it is dissolved in 2 c.cm. of dry chloroform; a blood pipette delivers 0.02 c.cm. of this solution into a 1 cm. Lovibund cell and the volume is made up to 0.5 c.cm. Two c.cm. of antimony trichloride in dry chloroform (Carr-Price reagent) is added from a B.D.H. automatic pipette; if a blue colour appears it is quickly matched in a Lovibund tintometer with blue and yellow glasses; similar tests are made until the content of the cell is matched by Lovibund blue units, and the necessary yellow glasses. The calculation is made as follows:—

Five blue units \times 2.5 volume of reaction mixture
 \times (2) amount of chloroform.

Amount giving 5 blue units \times grammes of liver (5).

Supposing 0.2 c.cm. gave five blue units, then—
 $\frac{5 \times 2.5 \times 2}{0.2 \times 5} = 25$ blue units per gramme of liver.

When a large number of blue units is present it is necessary to dissolve the evaporated residue in a greater quantity of chloroform, such as 5 or 10 c.cm.

Most of the livers of the children were checked against rabbits and bullocks' livers. The former ranged from 95 to 220 blue units per gramme, whereas the latter ranged from 1,250 to 2,350 blue units per gramme. This is not an exact check but it serves as a fairly satisfactory control when there is little or no vitamin A in the livers tested.

Seventy-seven livers have been tested; four were from stillborn children and the others from children of various ages.

Stillborn children

The four stillborn children were from very anæmic mothers who were between the seventh and eighth months of pregnancy. The results were :—

Blue units in gramme of liver.	Mother's hæmoglobin index.
350	45 per cent
25	anæmia ++
40	50 per cent
5	45 per cent

This shows great variation in the amounts of vitamin A in the livers of those stillborn children; but there is no correlation between the blue units and the degree of anæmia of the mother.

Livers which showed the highest blue units

The livers of the 73 children were in most cases from children who had died within a few days of entering hospital. The livers which showed the highest blue unit values were :—

Age.	Sex.	Cause of death.	Blue units per gramme.
12	M.	Endocarditis	155
10	M.	Killed in motor accident.	125

The boy who died of endocarditis had been in hospital for some time and had been well fed. The boy killed in the motor accident appeared well nourished but he belonged to the working classes and possibly about 125 blue units may be taken as a standard for this class of persons in the tropics, who usually live on diets containing little or no vitamin A and not large quantities of its precursor.

Livers which showed no blue units

There were 15 livers in which not a trace of blue appeared in the mixture containing the extract from 2 grammes of liver, the maximum

amount used in these tests. The following table gives a few details of those :—

the amount of improvement the skin eruption had undergone during the stay in hospital,

Livers showing no blue units in 2 grammes

Number	Age	Sex	Clinical condition	Degree of emaciation	Length of stay in hospital
1	10 months	F.	Bronchitis, malnutrition with œdema	+	2 days
2	3 weeks	M.	'Congenital syphilis'. Mother's Wassermann + +.	+	2 "
3	8 years	F.	Nutritional œdema	?	2 "
4	1 year	F.	Colitis	+	7 "
5	4 weeks	F.	'Prematurity'	+ +	5 "
6	12 years	F.	'Phthisis with œdema of hands and feet	+	4 "
7	4 "	M.	Chronic diarrhœa	0	8 "
8	2 "	F.	Enteritis and marked phrynoderma	+ +	6 "
9	15 "	M.	Ankylostomiasis and anæmia	?	5 "
10	5 "	M.	Brain abscess	0	7 "
11	6 months	F.	Infantile debility	+ +	3 "
12	6 "	M.	Gastro-enteritis	+ +	4 "
13	17 years	F.	Phthisis	+ +	10 "
14	5 "	F.	Anæmia, keratomalacia and phrynoderma	+	4 "

It will be noticed that the livers of three children with œdema showed no blue units, two of these (numbers 1 and 3) were typical cases of nutritional œdema. The parents of number 6 were indigent and it is probable that she had been poorly fed.

There were four cases of 'enteritis' (numbers 4, 7, 8 and 12) and two of these, numbers 4 and 7, had been in hospital for a week or more and had received cod-liver oil and other substances rich in vitamin A; and it appears a justifiable conclusion that vitamin A is not readily absorbed from a disordered alimentary tract.

There were only two patients who are recorded as showing marked phrynoderma, namely numbers 8 and 15, and the latter patient had keratomalacia.

Two patients (numbers 9 and 11) might equally well have been diagnosed as suffering from malnutrition.

Thus in 11 out of the 15 patients there was definite evidence of malnutrition or defective absorption.

The diagnoses in the four remaining cases were congenital syphilis, prematurity, brain abscess and phthisis.

Livers showing blue units

It is the routine practice in the hospital, to which most of the children had been admitted, to give all patients adequate amounts of fish-liver oils, or other preparations rich in the fat-soluble vitamins; consequently positive antimony trichloride tests with the livers of children who have been in hospital for many days are of little or no significance except that it may indicate that satisfactory absorption has taken place.

Eight patients, who had varying degrees of phrynoderma, had livers which give various numbers of blue units per gramme, but unfortunately no records were kept which indicate

There was a patient, aged 7, who had phrynoderma and keratomalacia and the liver showed 35 blue units per gramme, but the child had been in hospital for 10 days and appears to have died of a terminal bronchitis, and during the stay in hospital had received considerable amounts of preparations containing vitamin A.

It is noteworthy that the only three cases of nutritional œdema in this series also showed an absence of blue units.

Discussion

Many of the poorest class children in Ceylon are weaned to a diet poor in proteins and deficient in all vitamins, and it is not astonishing that various signs and symptoms of malnutrition are prevalent among them. In many cases the deficient diets produce debility paving the way for infections which lead to death.

The œdemas of malnutrition are usually attributed to a deficiency of vitamin B, and in many cases there is also a deficiency of proteins, and probably this occurred in the three cases reported here, but the fact that vitamin A was also deficient without the presence of signs usually attributed to this deficiency serves to show that a human diet which is deficient in one respect is often deficient in many others; and further that the absence of any particular signs does not necessarily exclude any particular deficiency.

The results in cases of enteritis indicate a defective absorptive power of the alimentary tract for fat-soluble vitamins; this is in accordance with the general experience that fats are not well absorbed when there are digestive disturbances. Carotene, the precursor of vitamin A, may be more easily absorbed, and, if so, is indicated in cases of enteritis; this may explain the widespread use of extracts of leaves in diarrhœas and dysenteries among the masses of the tropics.

A SYNCOPAL FORM OF ANGINA PECTORIS

(AN ELECTROCARDIOGRAPHICAL STUDY)

By J. C. GUPTA, M.B. (Cal.), M.D. (Cologne)

GALLAVARDIN (1922) described a form of angina pectoris which was characterized by attacks of syncopal syndrome something like that of Adams-Stokes'. He considered these in relation to a temporary vagal inhibition which is exaggerated in this condition. Such cases are, however, very rarely met with. The following case therefore seems to be worth reporting :—

The patient was a retired clergyman, aged about 56 years. One afternoon at about 2 p.m., while attempting to catch a train for which he was waiting on the platform, he felt vertigo and giddiness and fell down unconscious. He remained in this condition for more than two hours. On admission into the hospital he was still unconscious and had a pulse rate of about 30 per minute and a blood pressure of about 98/60 mm. Hg. After atropine and cardiazol injections, he soon regained consciousness and began to complain of pain in his chest behind the sternum. The pulse rate rose to about 60 per minute. The blood pressure too showed a rise of about 130/90 mm. Hg. Five months ago, he said, he had a similar attack of momentary loss of consciousness which was overlooked at that time.

The general condition of the patient remained fairly good thereafter. The precordial pain was all that he complained of. The pain was located in the right side of the chest close behind the sternum. It came at intervals of about 15 to 20 minutes. It was of a spasmodic character, 'twisting' in nature. It had a tendency to radiate towards the suprasternal notch. The

(Continued from previous page)

Cramer (1933) has reported some experiments on rats in which he has shown that when diets are deficient in vitamin B, there is defective absorption of vitamin A, and this may lead to xerophthalmia. This suggests that there are interactions among the vitamins, and whatever signs and symptoms may be present in all cases the correcting diets should be ample in all constituents.

Summary

A short description is given of a method of determining the amount of vitamin A in livers by the antimony trichloride test.

There was great variation in the numbers of blue units shown with the livers of stillborn children.

Fifteen out of 63 livers showed no blue units.

Four of these livers were from children with 'enteritis' and seven from children showing other signs of malnutrition.

characteristic radiation along the arm was absent. He did not feel any pain during sleep which was undisturbed owing to a soporific he was taking.

Physical examination revealed an emphysematous condition of the chest. The heart was more or less centrally placed. There was no apparent enlargement. Heart sounds were almost inaudible. There was no oedema or rise of temperature. Blood examination showed a slight degree of anæmia, hæmoglobin 50 per cent, and 2,900,000 red cells; the Wassermann reaction was negative. Biochemical examination gave a practically normal picture. Urine examination was negative. An x-ray examination of the chest showed no abnormality.

An electrocardiographical examination was undertaken on the third day after the attack. It revealed the cardiac nature of his troubles (see later).

As he showed no further alarming cardiovascular reactions, he was treated with injections of grape sugar to improve his cardiac condition, and he left the hospital after about a fortnight.

He was readmitted into the hospital after a fortnight with a similar history of another cardiac attack with loss of consciousness associated with convulsive movements of the limbs. This time too he complained of pain in the chest which was very similar to that described above. An electrocardiographical examination undertaken this time also revealed an exactly similar picture.

Comment

The electrocardiograms were very peculiar and, from the point of view of diagnosis, of the utmost importance. The ventricular complexes in leads II and III were of abnormal amplitude, notched near the apex of the extremely deep S deflections and were also widened beyond 0.12 seconds. The T and the main ventricular deflections were in opposite direction with respect to each other. The S-T segments were well above the iso-electric line. In short, in these two leads the picture resembled very much a right-bundle-branch block. The lead I was, however, very atypical. The amplitude of excursions was very small. The complexes were widened and thickened and the T deflections were almost iso-electric. The whole picture taken together was thus atypical for a pure right-bundle-branch lesion.

Mahaim (1927) has drawn attention to the fact that pure cases of right-bundle-branch block may be comparatively rare to find in as much as a clean severance of the right-bundle branch is not usually seen in human pathology analogous to that in an experimental animal. More commonly, a mixed type of right-bundle-branch block may be obtained clinically. From an anatomical consideration this seems very reasonable, as will appear from the accompanying diagram. Mahaim has described two different types of right-bundle-branch lesions: 'Bloc mixte de la branche droite a type anterieur' and 'le bloc mixte de la branche droite a type posterieur' (a mixed anterior type and a mixed posterior type of right-bundle-branch block). These can be recognized in electrocardiograms. In the first case the amplitude of excursions is very high in leads II and III, and lead III may be small and atypical, while in

the latter case the leads I and II may be large and lead III comparatively insignificant.

case becomes clear. The shaded area in the diagram may represent the localization of the

Fig. 1.—The electrocardiogram. Three leads. Note especially the widening of Q-S; notching at the apex of the main ventricular deflections; 'T' waves in directional opposition to the main complexes. The picture is suggestive of a right-bundle-branch block. The lead I is atypical. It is inferred that the bundle lesion is a mixed one affecting the right branch and also the anterior part of the left-bundle branches. These are in the distribution of the arteria limbi dextra branch of the left coronary artery.

Fig. 2.—A schematic diagram to show the vascular supply of the conducting system. The probable localization of the lesion in mixed right-bundle-branch block is shown. The shaded area represents the ischemic region and the darkened vessels the affected vascular zone.

In the light of the above facts, the interpretation of the electrocardiograms of the present lesion and the obliterated artery of the affected vascular zone. The arteria limbi dextra branch

of the left coronary artery supplies the right-bundle branch, exclusively, and a twig from this latter supplies the anterior portion of the left-bundle branches; hence the name 'anterior type'. Consequently, if it is assumed that the lesion is central to the branch supplying the left-bundle branches, it is easy to understand that the lesion must be of a mixed variety affecting the portion of the left-bundle branches as well.

This seems to be the explanation of the case so far as can be made out from the electrocardiographical examination. In the absence of any marked cardiovascular reactions, which are usually a necessary accompaniment in cases of coronary thrombosis, one is certainly justified in excluding a diagnosis of coronary occlusion in this case.

It remains still to explain the clinical symptoms of the case in relationship to the electrocardiographical findings: apart from the precordial pain, the most outstanding symptoms of the case were (a) history of attacks of loss of consciousness which is prolonged to over two hours in one instance, and (b) the bradycardia which is associated with this. One would be tempted to bring these in relationship to Adams-Stokes' syndrome. The loss of consciousness in Adams-Stokes' syndrome, however, is very transient, since it is a temporary ventricular asystole which is the direct cause of a temporary anæmia of the brain and the loss of consciousness results from this. An asystole of the ventricles extending more than 10 seconds is incompatible with life. A complete loss of consciousness in Adams-Stokes' disease lasting for two hours is, in fact, unknown.

It is more reasonable to suppose that the attacks in the present case may be of the nature

of vasovagal fits (Thomas Lewis, 1933) and of, essentially, a vagal phenomenon. It is quite possible that areas in the neighbourhood of the ischemic zone, as shown by the shaded lines in the diagram, have been rendered hyper-irritable. This has caused a stimulation of the vagal nerve endings. Thus, the loss of consciousness, and also the temporary bradycardia, may be looked upon as reflex effects in consequence of these. Heimann (1929) believes that, in certain acute myocardial processes, a transient heart-block may be brought about in this way, possibly due to a direct spasmodic contraction of the artery supplying the bundle of His. Gallavardin also suggested a similar interpretation to explain his cases of a syncopal form of anginal attack.

Conclusion

Thus the whole case is explained. We have a very remarkable case of anginal attacks associated with loss of consciousness and possibly a vagal inhibitory block. A mixed right-bundle-branch block, anterior type, has given us the clue to a diagnosis.

I beg to acknowledge my sincere gratefulness to Dr. I. Basu, visiting physician, Carmichael Medical College, for his kind permission to study this case in his wards and to publish it.

A Mirror of Hospital Practice

A CASE OF TICK TYPHUS AT ALLAHABAD

By R. N. BANERJI, B.Sc., M.B., B.S., R.B.
Allahabad

TICK TYPHUS is comparatively rare in this region, specially in the plains. I have reported cases of tick typhus previously as it is believed that this disease is seldom observed in the indigenous population.

S. W. H., aged 63 years, male, had a sudden onset of fever on the 9th October, without prodroma, but with chill and headache. He was quite well before the attack. He got pains in the back and limbs and the temperature rose to 102°F. on the second day. On the fourth day of illness a papular rose-coloured rash appeared on the limbs, it faded on pressure and did not itch and it soon became generalized, affecting the trunk, extremities, the palms and soles and a little on the face. There was none on the scalp.

This rash was first red, then deep brown and later on did not fade on pressure. Some of the spots were from

4 to 8 mm. in diameter. At this stage the patient developed marked insomnia, showed signs of toxæmia,

had abdominal distension and developed hiccough which persisted for nearly four days. He looked very ill

and was restless. Constipation was present almost throughout; he was never unconscious but the temper was irritable, and he was apathetic. The temperature was of remittent type, ranging between 101° and 103°F., and the pulse was comparatively slow all the time. On the 8th day of his illness a few dry sounds and moist râles at the bases were noticed on examination of the lungs and he had a slight cough, but this cleared up by the 14th day. On the 15th day the temperature fell to normal, almost by crisis, and the next day the maximum was 99.2°F. Convalescence was rapid and uneventful.

During the illness the patient had œdema of the feet which rapidly cleared up as soon as there was remission. The urine during the fever showed albumin and casts but within two days of the remission it was normal. The blood was examined on the 9th day of illness and the total leucocyte count was 13,800. Widal against typhoid, para A and different strains of para B were done at the brigade laboratory and were completely negative in all dilutions. The blood pressure was 127 systolic and 80 mm. diastolic, which was more or less the patient's normal reading as recorded for several years.

The rash was so characteristic that there was little doubt in the diagnosis; in the enteric group there is leucopœnia, while in this disease there is leucocytosis and in enteric the rash is only a few discrete spots on the trunk and never on the soles or palms. The whole body looked spotted and the possible confusion at the very early stage was with smallpox. The rash persisted after the remission of fever and is fading away gradually; it has not yet disappeared completely (7th November, 1936), there being brown staining at the site of the spots. The patient's past history is devoid of any serious illness; in fact he always kept good health except for minor dyspeptic troubles.

The first case of tick typhus reported in 1916 in the *Indian Medical Gazette* was that of Major-General Sir John Megaw at Lucknow whose case was observed by me and whose blood examinations during the illness were done by me. Since then I have been on the lookout for these cases and have seen occasional ones in the plains but have never been able to find the tick on the patient. I record my thanks to Dr. Lahiri, the attending physician, for permitting me to report this case.

[Note.—It is to be regretted that the opportunity was not taken of testing the patient's serum reactions to different strains of proteus X, with the object of confirming the diagnosis.—EDITOR, *I. M. G.*]

FATAL ANAPHYLACTIC SHOCK*

By ARUN CHANDRA NAG, M.B.

Bagerhat, Khulna District

A boy, aged 2½ years, had been suffering from irregular febrile attacks associated with enlarged spleen and liver and progressive anæmia for about nine months. After failure of oral treatment by drugs, the nature of which is not known to the writer, intravenous injection of urea stibamine (Brahmachari) were commenced by a local practitioner. The injections were given at intervals of three or four days and after the fifth, amounting to 0.025 gramme, the boy began to vomit, the face was cyanosed and in a very short time (about a minute) the eyelids and tongue became enormously œdematous.

He was given two subcutaneous injections, the nature of which is not known; this brought about rapid amelioration of the symptoms. The doctor in charge of the case having refused to continue the treatment the parents took the boy home.

After six or seven weeks the irregular fever and other symptoms returned in a more aggravated form and the boy was taken to another practitioner. He was given 0.025 gramme of urea stibamine intravenously twice a week without any unfavourable signs until, again after the fifth dose, a similar anaphylactic attack occurred. This doctor also refused further treatment.

For about two months the boy appeared well but once again the fever returned and he was brought back to the last doctor who gave an intramuscular injection of 0.05 gramme of neostibosan, which was repeated three days later. On the ninth day after the first injection the boy was brought back to the doctor with an abscess at the site of injection. He wished to open it but the parents refused and the child was brought to the writer a few days later. The abscess was opened and took a month to heal.

Towards the end of this period the temperature began again to rise and the blood gave a positive formaldehyde reaction. Urea stibamine injections (0.025 gramme each) were again given at intervals of three or four days. The first four injections caused no discomfort but after the fifth, which was also 0.025 gramme, the face and tongue became at once tremendously swollen, the child vomited, and there was marked cyanosis.

Immediately 5 minims of adrenalin chloride (Parke, Davis and Co.) and ½ c.cm. pituitrin (Parke, Davis and Co.) were injected hypodermically but it had no apparent effect and, in spite of artificial respiration being employed, the boy died in about ten minutes.

I am publishing this note in the hope that some explanation as to why this boy exhibited the same symptoms on three separate occasions may be forthcoming.

[Note.—Attacks suggesting anaphylactic shock are not uncommon in patients under treatment by some of the pentavalent compounds of antimony. Napier collected notes on 13 cases and reported them in the November 1926 issue of this journal. He also referred to his own experience. In most of the cases the untoward symptoms followed the administration of urea stibamine, but as this was the drug most widely used at that time no special significance need be attached to this observation. Reports of such occurrences are much rarer than they used to be. Since neostibosan has been the principal drug used at the Calcutta School of Tropical Medicine these reactions have become very rare in our experience.

The attacks usually occurred after four or five injections, as in this case, but here the exceptional feature is that the patient reacted severely on three separate occasions and that the last reaction was so severe that he died; death is a very rare occurrence, recovery being the rule even after attacks that present very alarming symptoms.

It seems possible that the intervals between injections in this case were so long that the patient, instead of becoming desensitized, became increasingly sensitive to the drug.—EDITOR, *I. M. G.*]

MAY

THE NUTRITIVE VALUE OF INDIAN FOODS AND THE PLANNING OF DIETS

NOWHERE in the world has the recent revival in the study of nutrition had more important repercussions than in India. There is abundant evidence that a very large proportion of the population is undernourished and that this undernourishment not only affects the mental and physical energy of the individual but increases the morbidity and mortality of the multifarious infections to which he is subjected. Further, the more the matter is investigated the more sufferers from diseases due to specific food deficiencies do we recognize. On the other side, we have the very low economic status of the population as a whole, a common factor in the nutrition problem in almost any country but of exceptional importance here, and in addition innumerable racial and religious traditions and prejudices which complicate every attempt towards dietary improvement.

There is a tendency in this country to pause a little while before following any new medical 'fashion' and, though this sometimes saves us much wasted effort, as many of these 'fashions' are soon played out and forgotten, it sometimes leaves us a little behind other countries in the adoption, and the adaptation to our own particular conditions and needs, of genuine scientific advances.

For many years pioneers such as Sir Robert McCarrison have been trying to make India nutrition-minded, but it is only during the last few years that even the sanitarian has been impressed with the all-importance of the nutrition in determining the health of the people, and the practitioner would be even more behindhand had his interest not been stimulated by the spectacular, but also very important, recent work on vitamins.

The complaint is often made that this centering of attention on the 'protective' substances in dietary, i.e., vitamins and mineral salts, has withdrawn attention from the equally important energy-yielding substances, the protein, the fat and the carbohydrate. There has of course been a tendency to concentrate on the former substance, but the net result has been a focusing of far more attention on the subject of dietary as a whole. The worst side of the vitamin boom has been its commercial exploitation, as, even though the extensive advertising of vitamin preparations does help to draw attention to these important food factors, it also helps to create a wrong impression in the minds of not only lay but also medical readers.

Only a short time ago we deleted the following sentence from an otherwise quite useful contribution which has actually appeared in the *Gazette*:—'The patients were all poor and could not afford expensive patent medicines, such as vitamins, etc.' A more absurd misconception it would be hard to imagine, but it is quite easy to see how it may come about if a medical man allows his post-graduate reading to consist solely of a perfunctory perusal of commercial journals and trade circulars.

There is, however, no doubt that to-day in India there is arising a genuine and widespread interest in nutrition, and it has immediately become apparent that we are far behind, not only most Western countries but also many Eastern countries, in the matter of literature and data on this subject. There are innumerable American and some excellent English books* on dietary, but most of these, except for the teaching of general principles, are of very little use to the worker in India. In the first place, the dietetic requirements of the people of India are not the same, either quantitatively or qualitatively, as those in temperate and cold countries, and attempts to draw up standard diets without appreciating this fact would lead to both waste and an unsuitable diet. Again, without the data available for foods peculiar to India, the dietitian is completely at a loss as he will not find in the analytical tables in the textbooks on diet any mention of the vast majority of the food substances eaten by the people here.

Data regarding the composition of various foodstuffs eaten in this country have been accumulating; the Nutrition Institute at Coonoor has devoted much of its energies to this important subject for a number of years and has published some of its findings from time to time, but recently the director, Dr. W. R. Aykroyd, has collected the available data regarding the food value, the protein, carbohydrate and fat, and the mineral and vitamin content of a very large number of Indian foods, and has tabulated them. This table has been issued by the Government of India in the form of a 'health bulletin'† so that this collected information is now available to anyone who is interested

* Of these one of the best known is Robert Hutchison and V. H. Mothram's *Food and the Principles of Dietetics* (Edward Arnold and Company, London, pp. xxviii plus 634. Illustrated. Price, £1-1-0). The eighth edition has just been published. It is an invaluable mine of information on all subjects connected with diet in health and disease. All recent work has been incorporated and the influence of climate on diet is discussed. It is a particularly suitable textbook for the dietitian in India and, combined with Dr. Aykroyd's brochure on Indian foods as a local supplement, it should give him all the information he or she requires.

† The Nutritive Value of Indian Foods and the Planning of Satisfactory Diets. Health Bulletin No. 23. Published by the Manager of Publications, Delhi (Government of India). 1937. Pp. 48. Price, As. 2 or 3d. Obtainable from Thacker, Spink and Co. (1933), Ltd., Calcutta, and elsewhere.

and is prepared to spend the modest sum of two annas.

This brochure contains much other information that will be invaluable to those in India who have to judge or plan diets, whether they be medical men or otherwise. The general principles are dealt with briefly and figures are given for the caloric requirements of the average Indian. The author is on very sound ground when he says that the scale laid down by the League of Nations Health Organization is too generous for this country, and places the requirements of the average male doing 'easy-going agricultural or coolie work' at 2,500 to 2,600 calories. He places the protein requirements for a male adult at 65 grammes a day and the fat at 45 to 60 grammes: these figures are both below the European standard, but even these low figures are very often not attained in a diet that consists mainly of rice.

Of the mineral defects in the 'average Indian diet'—such a term is scarcely justifiable as the 'average diets' in different parts of India differ widely—that of calcium is the most pronounced, as often no more than 0.2 gramme, against the standard requirement of 0.68 gramme, is found. The iron requirements of the body are small and usually satisfied, but where there is loss of blood from any cause (*e.g.*, hookworm disease) or excessive demand (*e.g.*, pregnancy) the deficiency becomes patent.

Many dietaries are deficient in vitamin A on account of their very low content of animal fat. This deficiency Dr. Aykroyd suggests can be made up by taking leafy vegetables plentifully. He refers to the possibilities of red-palm oil as a valuable source of fat, and of vitamin A, on account of its high carotin content. The B vitamins are deficient in certain circumstances especially where the diet consists mainly of

milled rice, but this deficiency is easily remedied. The greatest danger of vitamin-C deficiency lies in the fact that milk is poor in vitamin C and that this vitamin is easily destroyed by cooking, but it presents no special problem in India, nor does vitamin-D deficiency which, though it does occur, is probably rarer than it is in other countries where the sunlight is not so active.

The main difficulty encountered by the nutrition worker is the economic one. Devise how you may, you cannot produce an adequate balanced diet for Rs. 3 per month, which is often all that is available. On the other hand, many diets that cost far more than this are still unsuitable, and it is ignorance rather than poverty that is the most important factor in determining malnutrition, as even the diet of the poorest is usually susceptible to improvement without additional cost. This point has been well brought out by Dr. Aykroyd. As a cheap addition to diets of children in institutions he has recommended 'skim milk', or 'skim milk' reconstructed from powder. Though this cannot be recommended for infants living on a milk diet, it is very suitable for the older children on a mixed diet, as it is little short of whole milk in its nutritive qualities and is particularly valuable on account of its relatively high animal-protein content; in these poor diets the fat must be made up by the addition of vegetable oils.

It is specifically pointed out that there are many gaps in our knowledge of the nutritive values of Indian foodstuffs, but enough is known to justify the compiling of this 'health bulletin'. Its publication will do away with one of the most serious handicaps under which the nutrition worker in India has been labouring.

Special Articles

PUBLIC HEALTH ASPECTS OF FILARIASIS IN INDIA*

By M. O. T. IYENGAR, B.A., F.Z.S., F.R.S.T.M. & H.

ALTHOUGH filariasis is a widespread disease in India we have not sufficient information regarding the exact distribution and incidence of the disease. Megaw and Gupta (1927) mapped out the distribution of the disease in India based on answers to a questionnaire sent to medical officers in various districts (*vide map*). According to them the disease occurs on the eastern sea-coast of India, on the western coast in Surat and from South Kanara to

Travancore and in a few discontinuous patches along the Gangetic basin. As this map was constructed not on field enquiries but only on opinions of medical officers, it is not possible to estimate with any degree of accuracy the comparative intensity of filarial disease in different parts of India.

Sundar Rao has, in an unpublished article, worked out the distribution of filarial infection in India which is based partly on a rapid survey of some towns and, to a larger extent, on the examination of blood films from convicts in jails. The distribution of the infection in India, according to Rao, corresponds closely to that of the disease as shown by Megaw and Gupta.

A few investigations in local areas have also been carried out as, for example, in Cochin by Cruikshank and Wright, in Bihar and Orissa by Korke, in Puri by Das, in Trivandrum and

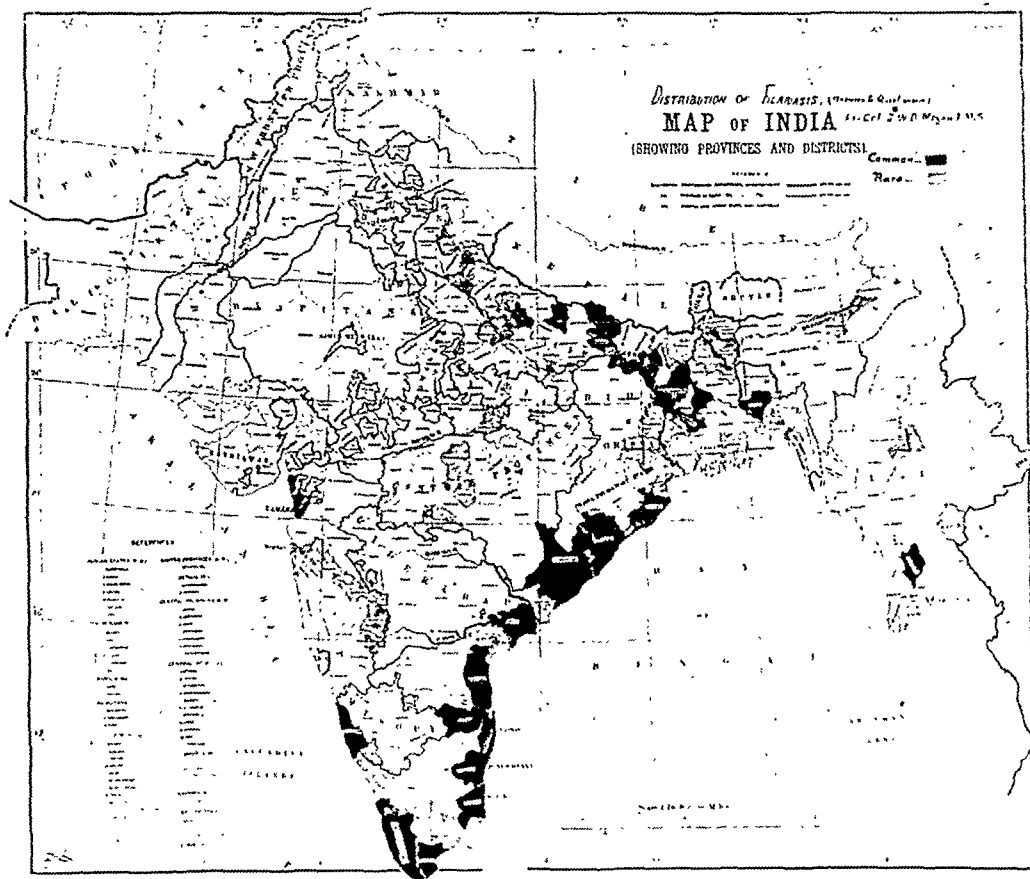

*Being a lecture delivered at the Public Health Society, Calcutta, on 24th February, 1937. This paper would in the ordinary course of events have appeared in the April issue, but was held over as that issue was a special tuberculosis number.

Travancore by Iyengar, in Saidapet near Madras by Pandit *et al.*, and in Patnagarh by Rao.

In connection with field studies on filariasis it is necessary to differentiate between the occurrence of filarial infection. In an endemic area there are three classes of persons—those with filarial infection, those with filarial disease and those with neither filarial infection nor filarial disease. There is a certain amount of overlapping in the first two groups, those with filarial infection and those with filarial disease, because a small percentage of the population may have both filarial infection and filarial disease. The percentage incidence of persons with signs or

filarial disease, care being taken to ensure that those having both characteristics are not counted twice. Data for the calculation of the endemicity rates for different parts of India are not available except in a few isolated instances.

Another important void in our knowledge is in regard to the distribution of the two types of filarial infection in India, namely, *Filaria malayi* Brug, and *Wuchereria bancrofti* (Cobbold). The earlier records are not entirely reliable because any infection with microfilariæ was generally put down as *W. bancrofti*. The microfilaria of *F. malayi*, which was described from the Dutch East Indies ten years ago, has since been observed to occur in some parts of India. As

Map showing distribution of filariasis in India.

symptoms of filarial disease constitutes an adequate measure of filarial disease in the community. Similarly, the percentage incidence of persons with microfilariæ in their peripheral blood at night gives the filarial infection rate. Neither of these rates will, by itself, however, give an accurate idea of filarial endemicity in the locality. A proper measure of endemicity in any area as shown by Iyengar (1933a) should therefore be a combination of the two factors, the incidence of filarial infection and the incidence of filarial disease, both these factors being investigated simultaneously. The filarial endemicity rate is the number of persons in the community (expressed as a ratio per hundred) who exhibit either filarial infection or

far as we know at present *F. malayi* infection has been found to occur in a few isolated areas, such as Balasore (Korke, 1929), Patnagarh (Rao, 1936) and Travancore (Iyengar, 1932). It is possible that its distribution is much wider than what is known at present*.

Apart from a purely academic interest, it is important to know the exact distributions of the two infections, as the measures of control are different in the two cases. This is because the transmitter of *W. bancrofti* infection is *Culex fatigans* while that of *F. malayi* is *Mansonioides*. These mosquitoes have different

* A focus of *F. malayi* infection has also been found in Cachar.—EDITOR, I. M. G.

breeding habits and distribution and, consequently, the methods of control would necessarily be different. A proper identification of the microfilaria is therefore of considerable public-health importance.

Causation of filariasis

The exact mechanism of the onset of filariasis is not yet clear but there can be no doubt that the condition is the consequence of an initial infection with *W. bancrofti* or *F. malayi*. The normal cycle of these infections is as follows: The infected person has microfilariae in the blood and serves to infect mosquitoes that may feed on him. Not all mosquitoes are capable of getting infected under natural conditions. The microfilariae of *F. malayi* develop best in *Mansonioides* and those of *W. bancrofti* in *C. fatigans*. In the mosquito host the microfilaria passes through its larval phases and reaches the final larval stage but there is no reproduction or increase in the number of filaria larvæ. The infected mosquito with full-grown filaria larvæ transmits the parasite when it bites man. In due course the recipient of the infection becomes a carrier and shows microfilariae in his peripheral blood. This carrier

Fig. 1.

again infects the mosquito. This is the normal cycle of the infection (figure 1). As the parasite does not produce, by itself, any pathological conditions in the host under normal conditions, no signs or symptoms of filarial disease occur at any state in this cycle of infection. The onset of filarial disease appears to be the result of a complication setting in over a filarial infection and, in most cases, this complication is produced as a result of a superimposed infection by pyogenic organisms, though in some cases a hyper-infection may also produce the same result. The source of this bacterial invasion is usually some septic focus in the body as shown by Acton and Rao (1929). The initial stage

of the onset of the disease is characterized by lymphangitis which is followed by a more chronic condition, such as elephantiasis.

When the disease progresses the infected person tends to become 'negative' for microfilariae in the peripheral blood, either because of a lymphatic block or through the death of the worm. This appears to be the explanation for the large proportion of persons with filarial disease being 'negative' for microfilariae. Such persons do not play any further part in the transmission cycle. The onset of the disease is thus a tangential branching off from the normal cycle of infection. The complications resulting from the bacterial infection are inimical to the parasite as the microfilariae disappear from the blood after the onset of disease symptoms. They are also injurious to the host since they produce pathological conditions in him.

Incidence of filarial disease and of filarial infection in relation to age

The data relating to an enquiry in certain endemic areas of Travancore have been analysed in order to bring out the incidence of filarial disease, filarial infection and filarial endemicity at different ages. The observations at Trivandrum were previously discussed by Iyengar (1933a). The incidences of filarial disease, filarial infection and filarial endemicity

Fig. 2

in different quinquennial age groups are shown in figure 2. It may be seen that the infection rate is lowest in the first age group (1 to 5 years) and that in the next age group (6 to 10 years) it rises to 14.5 per cent. In the succeeding age groups the infection rate fluctuates between 18 and 23 and the mean trend is a feeble rise. The filarial disease rate is zero in the first age group and from the second group onwards it rises steadily in the later age groups.

While the filarial disease rate and the filarial endemicity rate show a progressive rise in the

increasing age groups, the filarial infection rate does not show any such marked rise except in the first two age groups. The reason for this difference in the behaviour of the filarial infection rate on the one hand and of the disease rate and the endemicity rate on the other lies in the fact that the onset of filarial disease is followed by the disappearance of microfilariae from the peripheral blood. Thus in the higher age groups, although the endemicity rate is steadily rising, the infection rate does not exhibit a proportional rise with progressive age because of the increase in the incidence of filarial disease and the consequent fall in the number of persons with microfilariae.

Relation of filarial disease to filarial infection

The absence of microfilariae in the peripheral blood of the majority of persons suffering from filarial disease and the fact that the majority of persons with filarial infection do not suffer from the disease militate against the acceptance of a causal connection between the parasite and filariasis in view of Koch's first postulate. However when we consider the geographical distribution of filarial disease and that of filarial infection in Travancore there is a remarkable coincidence. But this by itself may not constitute a convincing proof of their relationship. It was therefore considered necessary to examine the data statistically to find out if there was any significant correlation between the filarial infection rates and the filarial disease rates of the different areas investigated in Travancore. It was found that the correlation was positive and significant*.

$$r = + 0.764 \pm 0.068.$$

Two types of filarial infections in India

As was mentioned previously we have two types of filarial infection in India, namely, *F. malayi* and *W. bancrofti*. The microfilariae of these two species can be differentiated on morphological characters. Although the relative distribution in India of the two species has not been worked out, the studies which I made in Travancore show that *W. bancrofti* infection is typically urban in distribution and that *F. malayi* infection occurs in rural areas (Iyengar, 1932). This is due to the fact that *W. bancrofti* infection is transmitted by *C. fatigans*, a mosquito most commonly observed in towns and only rarely in rural areas, while *F. malayi* infection is transmitted by the rural mosquito *Mansonioides*.

Both species are of pathological importance and are associated with filariasis in men. In *F. malayi* areas the chief manifestations are elephantiasis of the leg and hand; affections of the genitals, such as elephantiasis of the scrotum and hydrocele, are very rare. In *W. bancrofti*

areas, although affections of limbs are quite common, genital affections are also frequently observed.

Transmitter of *W. bancrofti* infection

The important transmitter of this infection, *C. fatigans*, is typically urban in distribution. The distribution of *W. bancrofti* endemicity is closely connected with the prevalence of *C. fatigans*. Areas with a high incidence of this mosquito have a high endemicity, while areas with a low incidence have a low endemicity. There is further proof of the relation between this mosquito and the occurrence of the infection in man, namely, that the infection rate among *C. fatigans* bears a close relationship to the infection rate in the human population. In Trivandrum which has endemic *W. bancrofti* infection, the infection rates observed in *C. fatigans* collected in 24 wards of the town show a significant positive correlation with the infection rate in the human population and the correlation coefficient is

$$r = + 0.5948 \pm 0.0888.$$

If we chart out the results, grouping the different wards into five groups according to

Fig. 3.

their filarial infection rates, we observe that the infection rate in the mosquito rises in direct proportion to the incidence of filarial infection in man (figure 3). The results show how the infection rate in the intermediate host, the mosquito, varies directly as the incidence of carriers among the human population and *vice versa*.

Areas with *W. bancrofti* infection

As already pointed out this infection is restricted chiefly to urban areas with great

*I am indebted to Dr. Raja for working out this correlation.

density of population. An explanation for it may be the fact that *Culex fatigans*, which is responsible for the transmission of the parasite,

finally discharge it into some natural depression, often inside the town itself. There is no provision for the proper treatment and disposal of

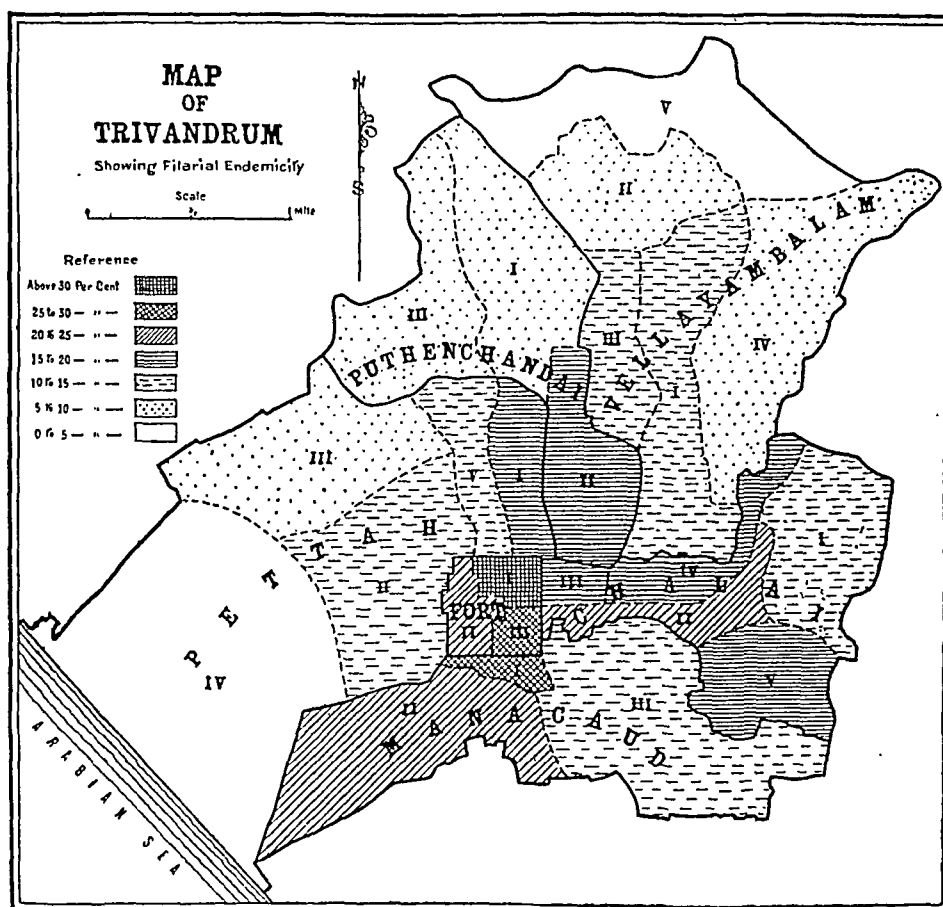

Fig. 4.

breeds in dirty water as, for example, sullage, and that, therefore, urban conditions afford more favourable opportunities for its multiplication than sparsely-populated rural areas. Even within a town, the incidence of this infection is, in consequence, higher in the central congested areas than in the outlying parts with a lower density of population. The distribution of filarial endemicity in Trivandrum is a clear example of this phenomenon (figure 4). There are various other factors that influence the endemicity of *W. bancrofti* infection as, for example, the lack of an efficient system of drainage, the level of the subsoil water and the nature of the soil. Climatic factors also have a bearing on the question inasmuch as a high atmospheric humidity and a certain range of temperature offer, as demonstrated by Rao and Iyengar (1930), the optimum conditions for the transmission of the infection. The extent of time during which such conditions prevail in a locality during the course of the year appears to influence the degree of its endemicity.

The common system of open masonry drains in Indian towns (*vide* figure 5) often does more harm than good. These drains merely collect the sullage from some parts of the town and

the sullage. In the absence of masonry drains the soil has a beneficial action on the sullage in that percolation of water freely takes place and, through the action of the soil bacteria, a clarification of the sullage is brought about. In consequence the conditions become less favourable for the breeding of *C. fatigans* than when crude sullage is left exposed in open masonry drains. In some urban areas every house has a masonry cess-pit in which sullage collects and is removed only at intervals. These pits help towards a prolific breeding of *C. fatigans*.

It is essential that a drainage scheme for the sullage of towns should be complete and should include its adequate treatment at the outfall. Imperfectly devised methods of land treatment of the effluent lead to waterlogging and provide excellent conditions for the breeding of *C. fatigans*. There is necessity therefore for rendering the drainage system proof against mosquito breeding at every stage.

The method for the control of the infection is by the control of the transmitter, *C. fatigans*. The most effective way of doing this is a proper system of subsoil drainage, but this is not feasible in all places in view of the cost. In the absence of such a system, temporary

measures for control will have to be carried out and these consist of the treatment with larvicides of all sullage drains, ponds and depressions holding dirty water.

One of the drawbacks in regard to schemes for the control of filariasis is that it is impossible to demonstrate any appreciable reduction in the incidence of the disease or of the infection within a short period of time. Local authorities who are responsible for providing the funds for such schemes are, on the other hand, likely to demand quick results. The minimum period necessary for achieving an adequate reduction in the incidence is at least ten years, mainly because the measures serve only to protect the new-comers and the uninfected persons in the population and have no influence on the persons who are already infected or those who have already developed the disease. Such persons will have to run through their normal course of the infection or of the disease. The only indication of beneficial results within short periods of time will be a reduction in the incidence of mosquitoes.

Transmitter of F. malayi infection

The important transmitter of *F. malayi* infection in India is *Mansonioides*. We have in India four species of *Mansonioides*, namely, *M. annulifera*, *M. uniformis*, *M. indiana* and *M. longipalpis*. The first-mentioned three species have been found by me to be infected with filariae in nature. Perhaps the most important of these species is *Mansonioides annulifera* which often occurs in very large numbers.

Mansonioides has a life history entirely different from most other mosquitoes. The female mosquito lays its eggs not on the surface of water but fixes them in clusters on the under

surface of the leaves of the water plant *Pistia stratiotes*. In nature, eggs are found only on the leaves of *Pistia* (Iyengar, 1933b). The presence of *Pistia* is an essential factor for the oviposition of *Mansonioides*. It is dependent on *Pistia* for yet another reason. Its larva unlike

Fig. 6.—Roots of *Pistia* with *Mansonioides* larvæ attached.

those of other mosquitoes does not come to the surface of the water to breathe but stays below the water surface attached to the roots of *Pistia* and obtains its oxygen from the air cavities of the root (*vide* figure 6). This it does by piercing the root tissue by means of a modified breathing siphon provided with strongly-chitinized structures at its tip adapted for the purpose of piercing the root tissue. *Pistia* appears to be the plant best suited for the *Mansonioides* larva and the only one which is utilized by it. When *Pistia* plants are removed from a breeding place, the larvæ die away rapidly and disappear from the breeding place, although other water plants may be present in the pond. The pupa of *Mansonioides* is also adapted for obtaining its oxygen from the root of *Pistia* and its breathing horns are strongly chitinized for piercing the root tissue.

Another factor that facilitates the breeding of *Mansonioides* is the presence of suspended organic matter in the water. The larva of *Mansonioides* leads a sedentary life fixed to the root of *Pistia* and it therefore depends for its food on organic matter in suspension. In the absence of such suspended organic matter the larva fails to develop (Iyengar, 1935). The organic contamination that provides this food factor in Travancore has been found to be the rotting coco-nut husk which is steeped in ponds for the manufacture of coir.

Where these factors do not occur, *Mansonioides* fails to breed and consequently the incidence of this mosquito is low. These factors therefore play a large part in determining the endemicity of *F. malayi* infection. The influence

Fig. 5.—Masonry drains in Indian towns breeding *Culex fatigans*.

of these factors in controlling endemicity can be cited here.

The presence of ponds is a factor in determining the incidence of *Mansonioides*. The larger the number of ponds, the greater would be the facilities offered for *Mansonioides* breeding. In a flat area as in Shertalai or the flat areas of Vaikam and Paroor, the number of ponds is large while undulating areas have very few ponds. This would explain the low endemicity in the undulating parts of Vaikam and Paroor taluks in contrast to the flat areas in those taluks where the endemicity is very high.

At the centre of towns situated in endemic *F. malayi* areas, as for example Alleppey, we observe that the central areas have a lower *F. malayi* infection than the outlying wards of the town and the rural areas outside the town. This may perhaps be explained as being due to a proportional reduction in the number of ponds with the increasing density of population. This is contrary to what has been observed in regard to *W. bancrofti* infection, where it was found that the infection rate increases towards the centre of towns; while *F. malayi* infection increases in a centrifugal manner towards the periphery of towns. As has already been explained *Mansonioides* breeds profusely under rural or semi-rural conditions and *C. fatigans* under urban conditions.

Endemicity of *F. malayi* infection is also determined by factors which control the presence of *Pistia*. In an area where ponds are connected with tidal channels, the movement of the water and the introduction of brackish or saline water into the pond have an adverse effect on the *Pistia* since it does not flourish in moving water or in water with much salt in solution. This would explain why areas subject to tidal influence although close to endemic zones are practically free from *F. malayi* infection. Another factor that controls the incidence of *Pistia* is flooding. In areas subject to extensive flooding during the wet season as, for example, parts of Ambalapuzha and Vaikam, all ponds and depressions are covered with the flood water and the *Pistia* in the ponds is washed away. When the floods subside, although there may be extensive breeding of mosquitoes, there is practically no breeding of *Mansonioides*. This would explain why flooded areas in Ambalapuzha, Vaikam and Paroor are comparatively free from *F. malayi* infection.

As *Mansonioides* is the only important transmitter of *F. malayi* infection, it would indicate that measures for the control of the infection should be directed against the principal vector, *Mansonioides*. The method of controlling a particular mosquito, omitting all others which are not of importance, is known as 'species sanitation'. *Mansonioides* being entirely dependent on the presence of *Pistia* for its propagation and for the growth of its larval

stages, it is possible to effect this 'species sanitation' by biological methods, namely, by removing the plant which acts as the host for

Fig. 7.—Pond with *Pistia* breeding *Mansonioides*.

the larvæ of this mosquito and which is essential for the growth of the larvæ (*vide* figure 7, a typical breeding place with *Pistia*).

An experimental scheme for the control of *F. malayi* based on this principle was started in a highly-endemic area in Shertalai taluk over an area of 25 square miles. The measures consisted in the removal of *Pistia* from all ponds and depressions in the area, but no attempts were made to remove the other water plants in the ponds. As a result of the removal of *Pistia* plants in the area, the incidence of *Mansonioides* in the area of operations was reduced to a very low figure, in striking contrast to the incidence of *Mansonioides* in the area outside this zone which served as control. Although there were quite a large number of mosquitoes (other than *Mansonioides*) in the area of operation, none of them showed infection with filaria larvæ which would indicate that, as a result of these measures, the transmission of the infection has been entirely stopped. On the other hand, in the control area a large number of *Mansonioides* was observed and a large proportion of these was found infected with filariæ which indicated that transmission of the infection was in progress in the control area.

Conclusion

The present position in India is that we have not the accurate data on filarial endemicity in different parts of India to enable us to compare conditions in one area with those of another. Filariasis is a widespread disease in India and, although cases of death due to filariasis are rare, the extent of incapacitation and

(Continued at foot of opposite page)

THE ANOPHELES SUNDAICUS INVASION OF LOWER BENGAL*

By R. SENIOR WHITE, F.R.S.E., F.R.E.S.

Malariologist, B. N. Railway

UNDER its former name of *Anopheles ludlowi* this mosquito was first recorded from Bengal

* A paper read at the Public Health Society, Calcutta, on the 22nd March, 1937.

(Continued from previous page)

of sickness due to it is very large. No one seems to have ever attempted to estimate the number of persons suffering from filariasis in India.

The respective distribution in India of the two filaria infections, *Filaria malayi* and *Wuchereria bancrofti*, has not been adequately surveyed. This information is of considerable public-health importance because measures for the control and prevention of the disease to be undertaken in *F. malayi* areas are entirely different from those to be employed in *W. bancrofti* areas. The control of the spread of *F. malayi* infection through the clearing of *Pistia* from ponds and other water collections carried out in Shertalai taluk mentioned previously has been successful and should commend itself to other areas with similar conditions. This type of control work is perhaps the first of its kind.

The position in regard to the control of filariasis in India is very disappointing. There is very little work done in India on the control of this disease which maims a large number of persons and causes considerable suffering. While it is nearly impossible to cure filariasis, it should be easy to control the spread of the disease through suitable measures, especially as the disease is restricted to comparatively small areas.

by James and Liston, from specimens collected at Frasergung, Matla and Konkondigee in the Sunderbans by Jenkins in November 1909, and from Port Canning itself by Gravely in December 1910.

These places are remote from Calcutta, only Port Canning is in direct communication with the city. The Sunderbans have always been notorious for their malaria, and apparently the findings were regarded as of no more than purely scientific interest.

A rude shock was given to this attitude by a virulent epidemic of malaria that broke out in the autumn of 1930 in the jute mill areas of Budge Budge and Chengail, situated on the left and right banks of the Hooghly, no more than 16 miles below the city. This epidemic was investigated by Iyengar, who found the causative species to be *A. ludlowi*, with at the time a sporozoite rate of 20 per cent. Spleen rates were up to 90 per cent in an area that had previously been found healthy ten years earlier in a survey by Khambhata.

This outbreak focused administrative attention on this insect, and the staff of the Department of Public Health, Bengal, was strengthened by one (ultimately three) survey unit to trace out the real distribution of the species in Bengal, and to record any further advances. A standing committee was formed, of which the writer is a member, and it is from the periodical survey reports of these units submitted to the committee that all later information in this paper has been collected.

The first fact elicited by the newly-appointed survey units in June 1931 was the discovery of heavy breeding at Falta, 25 miles from Calcutta, and connected thereto by a line of railway. The same month yielded the first instance of boat transport into the city. It was therefore decided to search trains at the various termini, and it was found that the K. F. Railway rakes stabled overnight at Falta (where there was now a severe epidemic) were bringing adult *ludlowi* to Majerhat terminus in large numbers, 7 per cent of them being infected. Searches at Sealdah in trains from Canning (where there was also an unprecedented malaria incidence) and Budge Budge, at Shambazar in trains from Hasnabad, and of the B. N. Railway local trains at Howrah all produced *ludlowi* by the end of September. This last finding led to the discovery of an unsuspected new breeding area at Uluberia, 20 miles out, where the train in question was stabled overnight. The initiation of this focus was traced to a country boat that had put into Uluberia from the Sunderbans.

These data at once led to suspicion that the Salt Lakes and the Majerhat swamps, outside the city, would become infested. It was experimentally proved that *ludlowi* could successfully breed out in both, but in spite of importation no natural breeding was discovered.

In February 1932, the Assistant Director, Malaria Survey of India, Col. Covell, examined the malaria situation in Calcutta city, and produced a report stressing the dangers of the situation.

During the winter of 1931-32 the Uluberia focus apparently became extinct, and breeding foci were no nearer to Calcutta than the original points of Chengail and Budge Budge, and Ghutiari Sharif, 19 miles out on the Canning line, but the following year registered another slow advance, which culminated in a 'cold-weather leap', breeding being discovered close to the city, on the western shore of the Salt Lakes, in December 1932. These cold-weather leaps appear to be related to the autumnal maximal breeding incidence just previously. It is seldom that science has an opportunity of studying an extension of its geographical range by any animal, which makes the present study not only one of great interest to the malariologist, but to the student of general zoology also. Discussing it with me shortly before he retired from this country, Sir Rickard Christophers said that he imagined that all species of animals, at their geographical boundaries, underwent a kind of peristalsis. The autumnal extension, and apparent winter recessions, of the *ludlowi* area certainly suggests this. Not only is Bengal the western limit of the species, it is also the northern, and here we can study an attempt by a purely tropical insect inhabiting a perennially equable littoral climate to colonize the subtropics with their much more definite seasonal changes.

The actual arrival of *ludlowi* on the city boundaries was an interesting phenomenon. *A. ludlowi* is a good traveller, as the railway records previously quoted have shown. But it is even fonder of boat than of train travel. The country-boat traffic of the delta approaches Calcutta by the following routes:—

(i) From down the Hooghly as far as the Sunderbans. These boats may pass through the city to points north of it, or may terminate at industrial points south of it, or unload in the docks and other localities within the city itself.

(ii) From the Matla river *via* the Bidyadhari river into the canal which circles the Salt Lakes (now too shallow for navigation) and divides into several branches within the city.

(iii) From Eastern Bengal generally *via* the Ichhamati river and the Bangor *khal* to join route (ii) at the south-east corner of the Salt Lakes.

Boats on routes (ii) and (iii) can pass out into the Hooghly to reach points north of the city through Chitpore lock. Boat traffic is of great density. Lines of boats extending over half a mile may accumulate and lie up at toll points, etc. The boats are covered country boats, often loaded many feet high with straw,

and afford ideal resting places to adult mosquitoes. In addition breeding of *ludlowi* in the bilge water is suspected, though I am not aware whether it has been actually proved. The boats are practically all owned by individuals, and their movements are subjected to no sort of control or regularity. Any attempt, however, to enforce legislation on the traffic would, it is believed, result in an increase in food prices in the city.

The journey of *ludlowi* to the city boundaries, that resulted in establishment of breeding within it, was accomplished by boat and not by train. The public-health department map, with its findings dated, shows that breeding was first found on the eastern shore of the lake, along which lies the line of the canal, and then, shortly after, at the point on the west where the canal enters the city. This dated set of findings conclusively proves that entrance was affected by circling the lake on three sides, and not to the western shore direct, as would have been the case if rail transport, by either the E. B. or B. N. Railways, had been the means. The insect, which had first been found (as adults) in the Kidderpore Dock area in November 1931, was again found in September-October 1932, and a search of the lock register clearly pointed to Falta as the importing source.

In the cold weather of 1932-33 *ludlowi* continued to spread on the western shore of the lake, and by February was breeding actually within Corporation limits. Transmission did not occur, naturally, until the rains, but in the third week of July 1933 there was a malaria outbreak in ward XXVIII (Beliaghatta). A mosquito infection rate of 6.6 per cent was accompanied by a human parasite rate of 59 per cent, and a child spleen rate which had been nil when taken in February was 9 per cent by July.

At the same time *ludlowi* was extending its footing on the right bank of the river around Chengail. The Uluberia focus, that had apparently died out in the winter of 1931, not only reappeared in November 1932, but by August 1933 had extended itself citywards for 5 miles to Bauria, accompanied by a sharp rise of malaria throughout this area.

The third cold weather again exhibited the '*ludlowi* leap'. First Belur, near the E. I. Railway workshops, 5 miles north of Howrah, was found infested in November, and before the close of the year infestation had been found on the edge of the French territory at Chandernagore, whilst a focus on the opposite bank at Shamnagar recrudesced after three years' apparent quiescence, actual breeding being found, which had not been the case in 1930. This instance, and that of Uluberia, suggests that though a focus once established may appear to become extinct during the subsequent cold weather, it is actually only dormant, and

a position once gained is never, in military parlance, evacuated.

The complete occupation of the deltaic area east of the Hooghly was apparently completed in 1934 and 1935. A focus at Godakhali, midway between Falta and Budge Budge, occupation of K. F. Railway borrow-pits up to Bishnupur, 8 miles south of Majerhat, and at several points along Tolly's Nullah were discovered. The Salt Lakes area was widely infested, whilst a vast stretch of country north-east of Canning stretching past Hasnabad to Swarupnagar on the Ichhamati was all found to be in *ludlowi* occupation. It is not certain whether this was only affected in 1934, for this tract had not been examined previously. We can have nothing but admiration for the work of the public-health department's survey units, but it is manifestly impossible for so small a personnel to examine the whole delta annually, hence foci discovered in later years may have existed earlier. Equally, it must be admitted, inability to examine all known foci each year may have failed to detect the evacuation of certain spots, though, as shown above, this I consider to be an unlikely occurrence.

The year 1935 completed the occupation of the Salt Lakes, even to central villages remote from the canal lines, 77 breeding places in this area being known by February 1936 as against 32 in the previous November, and of a group of villages on the Lakshmikantapur branch of the E. B. Railway. The number of breeding places actually within Corporation limits increased from three in March 1934 to 36 in March 1935. Dum Dum and Cossipore were found infested in April. These were undoubtedly new points. Ichapur Gun Factory was found infested in July. Diamond Harbour was also infested. In 1936 the most notable new breeding ground discovered was at Dakhuria, Ballyganj ward of the city being infiltrated by the adults produced. 1934 and 1935 were years of generally light malaria incidence in western Bengal, and the 1933 outbreak in eastern Calcutta was not repeated. But 1936, a year of general heavy incidence, especially on the western coast of the Bay of Bengal, produced a bad autumnal outbreak in eastern Calcutta. A sporozoite rate of 7 per cent in the mosquito brought spleen rates up to 52 per cent in Dhappa and 44 per cent in Pagladanga within Corporation limits. Transmission was actually occurring right up to the rather delayed onset of the cold weather in December.

Such is the story, up to date, of the *ludlowi* invasion of Lower Bengal. Throughout it has exhibited one significant phenomenon, the increasing adaptability to lower and lower salinities shown by the insect. Rodenwaldt and Essed give 12 to 18 per thousand as the most favourable concentration (pure sea water is 33 to 36 per thousand). Iyengar found the optimum at Budge Budge in 1931 to be 1.5 to 2.5 per

thousand, and even lower findings have since been recorded. At such values practically all the standing water around Calcutta would appear suitable, as regards salinity, for breeding. Neogi has, in fact, found it fourteen times in salinity of 0.1 per cent, with an optimum at 0.3 to 0.4 per cent. His upper limit of 27 per thousand closely agrees with similar Dutch findings of 30 per thousand.

Having recorded the facts, it is certainly open to us to speculate regarding their causation.

Covell suggests that in the years prior to 1930 there had been extensive clearance of the mangrove in the Sunderbans leading to increased breeding in the original focus. Enquiry from the forest department should enable this suggestion to be tested. It is certainly a fruitful one, it being well known how clearly *ludlowi* outbreaks in Malaya and the Dutch East are correlated with cutting down and bunding in formerly virgin mangrove areas.

Secondly, the progressive deterioration of tidal influence in the Salt Lakes, caused by the slow death of the Bidyadhari river, wants detailed tabulation from the mass of information that must be available in the records of the irrigation and public health engineer's departments, and also the Corporation. The seasonal salinity maps of the Bay of Bengal by Sewell show the following salinities at the head of the Bay :—

March—May	..	32	per thousand
June—August	..	30	" "
September—November	..	20	" "
December—February	..	30	" "

The season of the highest tides, which will penetrate further inland, is May—the period of maximum salinity—but even that is little above the maximum previously given for *ludlowi* breeding. Diluted as the farthest-flung tidal waters must be, the high tides of May-June can have little or no inhibitory effect on breeding. In the period of maximal breeding—the autumn—it is seen that *ludlowi* could comfortably (as regards salinity) breed in the sea itself far from land !

As regards changes in salinity in the Salt Lakes due to the gradual failure of tidal influence through the death of the Bidyadhari, averaging by years a table published by Neogi (though the points where analyses were made are not constant for the three years tabulated), we find, for points between Lansdowne Jute Mill and Bhamanghata lock as under :—

Year	Number of observations	Average salinity, per thousand
1926	4	17.31
1928	8	11.37
1935	6	0.51

Tidal influence therefore failed entirely between 1928 and 1935, i.e., in the years in which the *ludlowi* invasion of Bengal was accomplished.

The death of the Bidyadhari has been brought about by silting due to :

- (i) Bunds for fish culture.
- (ii) Bund reclamation for paddy cultivation.
- (iii) Calcutta's sewage outfall.

The rendering of the area from Matla to Calcutta suitable for *ludlowi* is therefore apparently an entirely man-caused phenomenon, and *ludlowi* malaria in this area is another case of 'man-made malaria'.

It is by no means to be assumed that this is so throughout the whole *ludlowi*-invaded area. I have read a good deal of the literature on the Hooghly, and cannot recall any recorded major changes in the last ten years between Chandernagore and Diamond Harbour, yet the left bank has been occupied by the insect from Shamnagar to Cossipore, and from Budge Budge to Diamond Harbour. The right bank, on the other hand, has only been occupied from Chandernagore to Belur, and for 5 miles above Uluberia. The deltaic area between the Hooghly and the Rupnarain, including the Damodar, is still free. Urban conditions in Calcutta and Howrah possibly prevent riparian infestation for some miles south of Cossipore and Belur, but why has the Budge Budge focus not spread northwards to Akra and Majerhat swamps? The latter were probably tidal before King George's Dock was built. Why have years of close watch on the Uluberia-Bauria focus revealed no attempt at extension west or east? Investigations on both sides of the insect's boundary at such points are most likely to yield the key to the inhibiting factors.

It is sometimes suggested that *ludlowi* had invaded Bengal before, and, having retreated then, may do so again. The evidence adduced for this is twofold. Brahmachari in 1912 recorded the insect as breeding in the Campbell Hospital tank from November to February of the previous cold weather. This tank is close to Sealdah station, to which the insect has probably been imported with some regularity from Canning for many years. The history of malaria in Canning in the autumn of 1911 may indicate whether *ludlowi* was unusually prevalent that year. In any case the occurrence is probably on a par with that in which *ludlowi* escaped from Schüffner's laboratory in the Sumatran highlands and bred in the vicinity for several generations before it died out. It has not, even with heavy breeding within two miles at Dhappa in recent years, again established itself in the Campbell Hospital tank.

The second piece of evidence is the record, by Graveley, of *ludlowi* at Chingrighatta on the Salt Lakes in February 1915. This record appears to be rather uncertain. Covell states that Christophers received certain specimens from Annandale about that time thought to be *ludlowi*, but which he found to be only *subpictus*, and in his Calcutta report Covell makes no

reference to Graveley's record, which in any case does not state whether the specimens were bred or captured as adults. If the latter, it must be recollected that the Central Lake Channel was probably open to Chingrighatta lock as late as 1915, and so would be used by country boats from the Sunderbans.

To my mind, there is no hope of *ludlowi* naturally evacuating the tract it has occupied in the last six years, and without human interference this vast area may be said to have been lost to Bengal as developable territory.

As regards human interference, in discussing this one must unfortunately pass from the realm of scientific to that of political discussion.

The original focus at Budge Budge has throughout the period from 1930 been controlled by the public health department, working with funds augmented by the local municipality and the jute mills there, the area protected being limited to that affecting the town and the mills; the E. B. Railway malaria section co-operating as regards work in their own area.

The Chengail focus was at first dealt with by the public health department, with funds augmented by the B. N. Railway and two of the four jute mills, and the district board. Later, the protection of this area was handed over to the B. N. Railway medical department (malaria section) who were, and still are, controlling the extensions of this focus at Uluberia, Fuleshwar and Bauria without any external financial aid. In consequence, part of this focus, around Bauria cotton mill, is not dealt with as it does not affect the railway. This makes all the more interesting the failure of this focus to extend up-stream, previously referred to.

The original focus at Falta was dealt with by the public health department, with, I believe, some financial contribution from the K. F. Railway. But this focus, as the map shows, has steadily spread outwards.

At Canning work is done by the district and union boards and by the E. B. Railway, but this being an area where the insect has certainly been established for over a quarter of a century, if it is not within the natural range of the insect there can be no more hope of eradicating it than of any other endemic species.

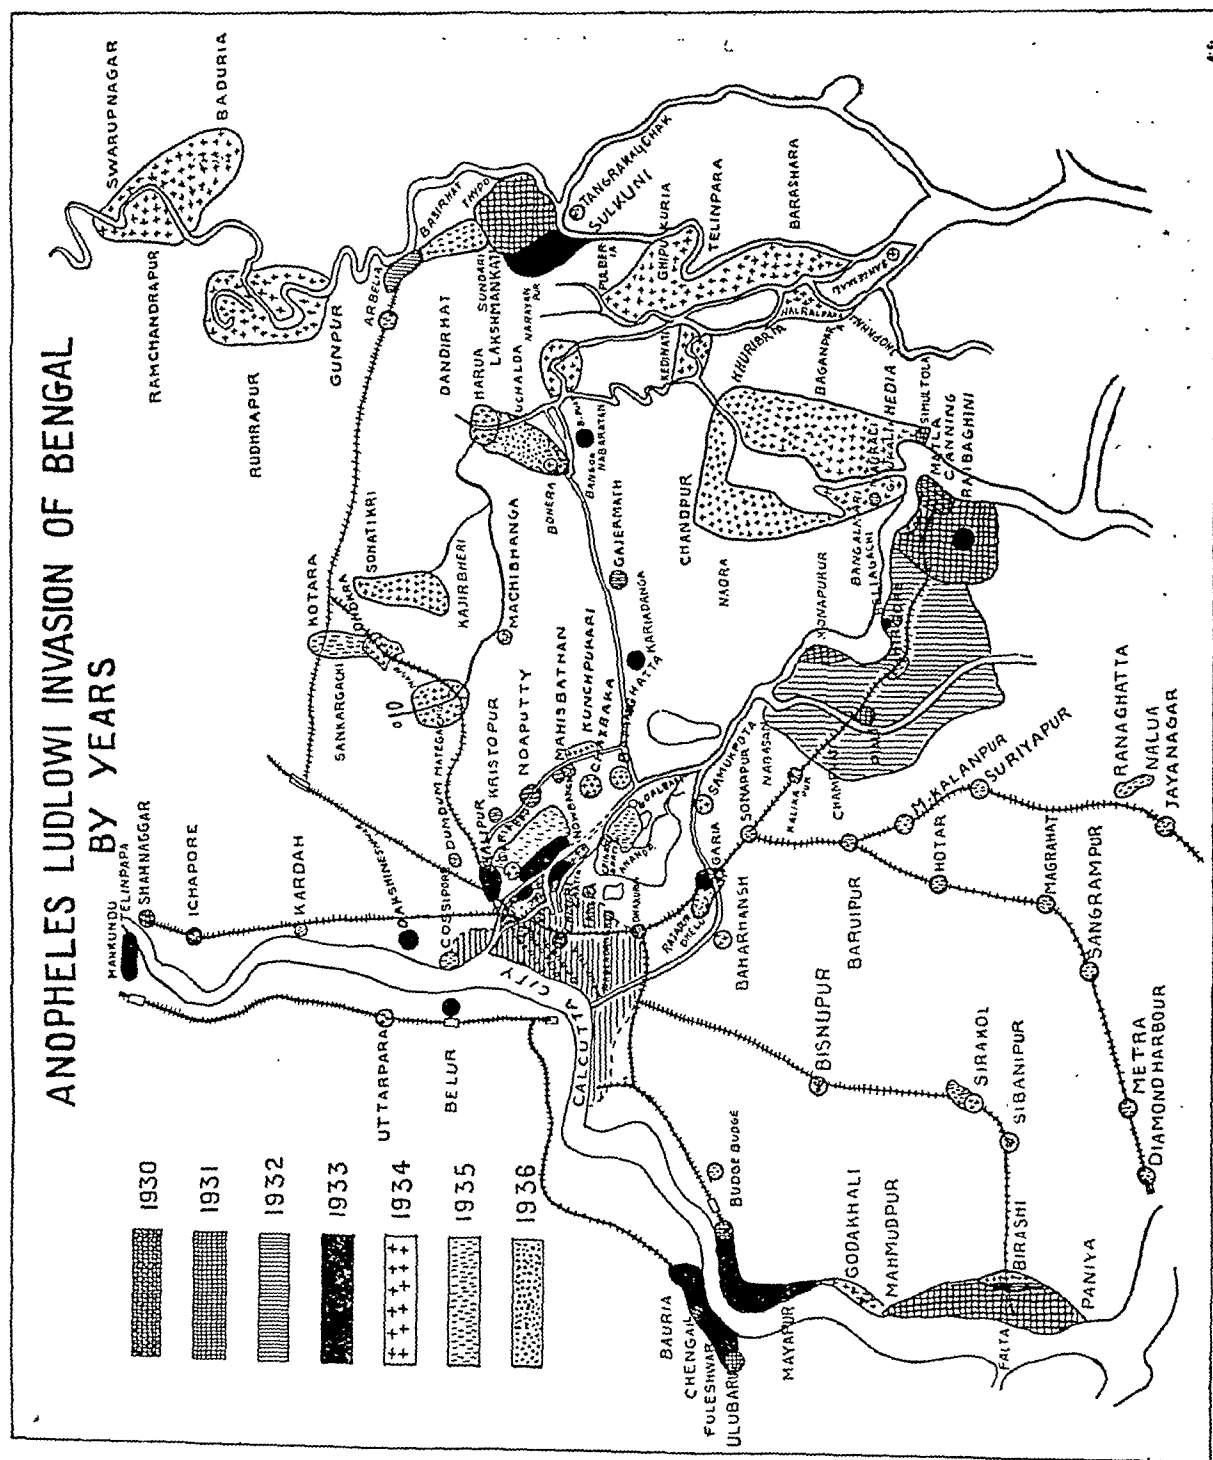

At Hasnabad the district board has made rather sporadic attempts at control. There being no major industrial interest there, results have been limited by financial considerations. At Belur the work has been from the start in the hands of the E. I. Railway medical department.

The story of the Salt Lakes focus is the most controversial. It is by far the most important, as it directly affects the city. The Corporation, though all along prepared to do work within their own boundary, have steadfastly pursued a policy of refusing to do anything one yard

beyond it. The district board, 24-Pergannas, is naturally financially quite powerless to do anything in and around the lakes. Thus Government struggled with the work unaided in that part of the lakes adjacent to the city, up till 1935, when they withdrew financial support from all active control measures and confined

last contributed to Government for work beyond their actual boundary.

As for the remainder of the invaded area shown on the map, it is rural, and no attempt has been made, nor is it financially possible to contemplate any attempt being made, to control these immense breeding areas by larvicides.

their efforts to survey work only. This left the lakes focus to increase unchecked, with results to the city in 1936 that have already been described. I understand that, following on the outbreak of last autumn, the Corporation has at

Are we then tamely to lie down to the permanent loss of these thousands of square miles? It is known that silty water is fatal to this mosquito. Repetitions of the very effective

FIRESIDE FANTASIES

By S. D. S. GREVAL

MAJOR, I.M.S.

LIVING ON AIR

Do the feeders on *dal* and rice get their full requirements of nitrogen from their food? In India there are millions of people who do not touch meat, fowl, fish or eggs and are too poor to afford milk or milk products. Yet they live and work. Some of them work hard. Where would you find a hardier syce than the one in the United Provinces? The rice in their diet may give them an excess of carbon but the *dal* does not appear to provide anything like a sufficiency of protein (containing nitrogen). For days together they will dispense with it altogether and live on rice made acceptable with chilli paste. Does the *dal* provide them with the subtle nitrogen binding factor which enables the natural order of plants producing *dal* (*Leguminosæ*) to bind in their seed nitrogen of air?

One of these days I may confirm my presumption with calorimetry and the basal metabolic rate. The item will be entitled *Fixation of atmospheric nitrogen by animals on leguminous diet*.

OPIMUM EATING

'He is seventy or two and seventy', I heard about a friend of my grandfather's, 'and yet he will thread a needle for you any day'. Glasses were then unknown. Fully ten years later I heard the same remarks about the same dear old grandpa. Age after 'seventy or two and seventy' stood stationary in the little village of K.K. in Ludhiana district of the Punjab. I do not know how long it had stood stationary before I heard the first pronouncement. The

(Continued from previous page)

North Budge Budge flood-flush scheme have been worked out by the engineering branch of the public health department for South Budge Budge and for the Chengail focus excluding Bauria. They await financial implementation. Such may one day be afforded, as the areas are industrial. But what of the Salt Lakes and the vast area east of the Ichhamati? Only a comprehensive irrigation and land reclamation policy, such as is advocated by the chief engineer of the public health department, can ever hold out any hope of eradicating, or even controlling, breeding. And in the way of such a policy, apart from finance, stands the serried ranks of vested interests in rice lands and fisheries that have so largely contributed to the spread of infestation.

I would plead for a commission of all departments of Government concerned—public health, irrigation, agricultural, and lands—to formulate a concerted scheme for legislation.

old gentleman had been a wrestler in the days of his youth. He had then worked hard as only a Punjabi farmer can work. His children and grandchildren had grown up and relieved him of his routine. Yet he would take the cattle out for grazing along the road or along the canal. Late in the afternoon he would take opium 'about the size of a mustard seed'. Perhaps at times he would take another dose later, if still up after the night had advanced 'a quarter' of the whole. He had done so for many years and would have probably done so for many more years had not a particularly vicious epidemic of plague claimed him.

'How long have you been here, Big Master?' I asked in my best Delhi accent of Urdu. 'For a century, Your Presence,' he replied in a melancholic strain. I had at last discovered in Rangoon in 1929 the grave of Bahadur Shah, the last of the Great Mughals. The Big Master had come with the Refuge of the World and the Emperor of Delhi to Burma in 1857. After the demise of the Emperor he had washed the grave stone, spread a cloth of silk and gold over it, and burnt incense near it. He would go on doing so as long as God gave him life and subsistence. The latter included a considerable amount of opium. His expression was indicative of contentment and benignity. His beard was long and hair longer. They were not snow white. Everybody who knew him had always seen him looking exactly as he looked then. A daughter of the Emperor, who was also traced, was, alas, not very communicative. She could have given a more precise figure for his age.

Grazing cattle are being looked after along the whole length of the Grand Trunk Road, as it passes through the Punjab, by old men who have retired from the Indian Army and are mostly 'seventy or two and seventy'. They have no literary inclinations, no diaries and no clear recollections of dates of births. Nearly all of them include opium in their daily ration.

Opium, taken in small quantities, after the retiring age, seems to keep off irritability, worry and the general wear and tear of the system. It is known definitely to prolong life in submarine disasters when the crew are entombed at the bottom of the sea with a very limited supply of oxygen.

One of these days I may confirm my presumption with the basal metabolic rate and reaction time. The item will be entitled *Reduction of catabolism and delay of dissolution under morphinism after retiring age*.

TENDER TIPS

Sag for four months in the year, if not six, is the staple diet of us farmers in the Punjab. It consists of leaves, tender stalks and tips of the mustard plant, picked freely from one another's farms, cut up fine and cooked for several hours. Occasionally, and for a brief period only, the gram plant serves the same

purpose. The *sag* is eaten with maize or millet chapaties. Buttermilk goes well with this dish as it does with every other dish in the Punjab.

We do well. Our physique, stature, expectation of life and numerical strength in the army are the highest in India. We hold our own, outside India too, better than our neighbours, near or remote.

Other feeders on tender tips also do well. Amongst the mammals monkeys live on tips. Their energy is well known. Even their growth, after reaching the adult stage, particularly in the male, does not appear to stop definitely. Amongst the aquatic animals which live either directly on aquatic vegetation, which is all tender tips, or on other animals which live on aquatic vegetation, the growth definitely does not stop at all. No codified dimensions for any type of fish, for instance, can be quoted to silence an angler when he is telling the tale.

The aquatic vegetation is more than tender tips. It is the original living substance untamed by cages of wood hardened and reinforced with minerals from rocks of the earth. It is the substance which came into being as an embodiment of life, in the choicest of mixtures of colloidal solutions of nitrogenous matter accumulated at the bottom of collections of water (we will not call these accumulations silt). It learnt to live and grow and reproduce itself on the minerals of earth, flavoured with minerals occasionally falling on earth from celestial space as meteorites. It is still doing so. The land plants have on them only spots which could claim a remote relationship to the

independence enjoyed by the aquatic vegetation. These spots are on the tender tips.

Aquatic vegetation is being utilized for human consumption but not for the purpose we are considering. In Scotland it is served free of charge in public houses as *dulse*. In Japan it supplements not very plentiful food resources of the country as a breakfast dish. Diabetics and slimmers use it as agar jelly sweetened with saccharin to combat the emptiness of the alimentary system.

Recently, work has been reported on the initiation of growth by mitogenic rays emitted by growing points and meristems. Into a narrow glass tube, with one end sealed, is thrust a root from a growing onion. The tube is pointed horizontally at another root, from another onion, similarly enclosed in a narrow glass tube but disposed vertically. Both the roots are still integral parts of their respective onions. A branch grows on the vertical root at the spot pointed at. The essential feature of the procedure is the pointing of the tip of one root to an area on the other root. Dimensional disposition in space is immaterial. The growth-producing influence (mitogenic ray) passes through glass. It is not a vitamin. Is there a fairly stable substance responsible for the emission of the influence? Is it an element like radium? One of these days I may confirm my presumption. Upon the process I have not yet decided. The item will be entitled *Acceleration and initiation of anabolism by mitosium*.

So much for the fireside fantasies. In Calcutta we keep fires in the winter just alight.

Medical News

PRESIDENTIAL ADDRESS DELIVERED BY MAJOR-GENERAL SIR CUTHBERT SPRAWSON AT THE SEVENTH SESSION OF THE MEDICAL COUNCIL OF INDIA, ON 12TH FEBRUARY, 1937

DR. YOUNG AND GENTLEMEN,

I welcome you here to-day to the seventh session of this council. Unfortunately since our last meeting we have lost one of our number by the death of Colonel Thorburn, a sitting member of the council. Colonel Thorburn had long experience of the frontier of India, in Afghanistan and in the Independent States of India, and he had but little more than a year ago been appointed to an office in the North-West Frontier Province well suited to his administrative abilities. We shall miss Colonel Thorburn from this council and in many other ways. You will presently be invited to express your sympathy with his widow.

We welcome back to the council Major-General Sir Frank Connor, now representing the Government of Madras, and we welcome a new member in Lieutenant-Colonel Dimond, the nominee of the Government of the North-West Frontier Province.

It is but three months since we last met; but there are a few matters of fresh interest and several items of former business, of the progress of which the council should be informed.

On the recommendation of this council the Governor-General in Council has notified the inclusion of the M.B., B.S. degree of the Rangoon University on the first schedule of the Indian Medical Council Act of 1933.

A proposal has been made to the General Medical Council for the recognition for registration of the medical degrees of the Universities of Calcutta, Rangoon and the Punjab approved by this council at their last session. This proposal will be considered by the executive committee of the General Medical Council at their meeting towards the end of the present month.

I explained at our last session the necessity of revising our Recommendations on Medical Education and informed you that the draft revised recommendations had been sent to the universities for their remarks. All the universities have now replied and their observations have been sent to you with the agenda for this meeting. The recommendations of the executive committee at their meeting yesterday have been laid on the table. I trust it will be possible for the council to consider those recommendations to-day.

As directed by the council at their last session the inspection of the Andhra University, including final examinations, has been carried out by our inspectors and the reports thereon were considered yesterday by the executive committee. The executive committee

decided to recommend to the council the further postponement of the recognition of the degrees of the Andhra University. The reports of the inspectors and the comments of the Andhra University thereon will be sent to members of the council so that the council may consider them with the executive committee's recommendation at a subsequent meeting.

A communication was received from the Andhra University suggesting a provision in the Act that a member representing a university should cease to be a member of the council, should he for any reason cease to be a member of the Faculty of Medicine of that university. Such a change would require an amendment of the Act and the proposal of the Andhra University is one of the points that should be considered later on if and when Government may undertake the revision of the Act. There are two other matters with which the executive committee have concerned themselves. One is about the teaching of obstetrics. The executive committee have addressed a questionnaire to all the universities asking information on several details of the practical instruction given in this subject. Their replies are awaited.

The other matter is the important one of the pre-medical scientific subjects. The executive committee consider that if these subjects were more efficiently taught by the science colleges, and taught also with a definite understanding that the student has a medical career in view, then it should be unnecessary for a medical college to teach them over again and to hold a pre-medical test examination. At our request the universities have furnished information about the courses of study and the examinations held by them for purposes of entry to their medical course, but we find the information insufficient and are addressing those examining bodies directly for further details of their syllabuses and the nature of their practical classes. We anticipate it will be necessary later to make an inspection of some of these courses.

Other inspections have also been the subject of your executive committee's consideration. We have now completed the first inspections of the courses of study and the final examinations of all the universities of British India that have medical faculties and it has been considered whether the time has now come to inspect not only the pre-medical scientific subjects already referred to, but also the medical scientific subjects, such as anatomy and physiology, and the instruction in these subjects, in greater detail. The executive committee yesterday decided that inspections of courses and examinations in the subjects of anatomy, physiology and pharmacology should be made during the present year and they have selected inspectors to that end.

A request was received from the Mysore Medical Council for the recognition under Section 13(1) of the Indian Medical Council Act, 1933, of the degree of M.B., B.S. of the University of Mysore. The executive committee decided to inform the Mysore Medical Council that a necessary preliminary to recognition by the Medical Council of India of this degree would be the inspection by our inspectors of the courses of study, examinations and facilities for teaching of the Mysore University and we enquired whether the university would be agreeable to such an inspection. In reply, the Mysore Medical Council have forwarded a copy of a letter from the registrar, Mysore University, to them, stating that the question of inviting inspection would be considered after the extension and improvements now in progress in the Medical College, Mysore, were completed.

The regulations proposed for this council will be before the present session. They have been the subject of long consideration both by Government and by this council and it is hoped that the present session will see them at last in finished form.

I referred at some length at our last session to our foreign relationships, particularly those with the Portuguese and French Indies.

It is satisfactory to know that the Portuguese Government have reintroduced the reciprocity

formerly existing between Portuguese India and some of our provinces. This means that medical men passed out by any of the universities of the presidencies of Bombay, Madras and Burma, or licensed by the College of Physicians and Surgeons of Bombay, or those passing degrees higher than the last-mentioned college obtained in the said Bombay Presidency, or even who have medical qualification of the schools of Burma equivalent to the course of the medical and surgical school of Nova Goa, can exercise their profession in this colony.

As regards French India the executive committee have decided to represent the case to the Governor of French India. Before doing so, they have asked for the view of the Provincial Medical Councils as to whether they wish to have reciprocity with French establishments in India, and, if so, on what conditions and also what action, if any, they propose in case the reciprocity is not agreed to by the French authorities. Replies are still awaited from most of the provincial medical councils. This matter will come before the council with the recommendations of the executive committee in due course.

I reported also to you at our last session that we had entered upon our duties under Section 13 of the Act and were in correspondence with the authorities in other countries, especially with those whose degrees are already on our Second Schedule. The negotiations have continued and though I do not intend at this moment to state the stage we have reached in regard to each country, I will review briefly the general position. The countries whose degrees are on our Second Schedule are other parts of the British Empire, and Italy and Japan. We have been in correspondence with the authorities of Ceylon, Hong Kong, the Straits Settlements, Malta, Newfoundland, New Zealand, South Africa, New South Wales, South Australia, Victoria, Alberta, Manitoba, the North-West Territories of Canada, Nova Scotia, Prince Edward Island and of Italy and Japan.

We have received no reply from Japan and with Italy our negotiations are delayed pending the conclusion of a new agreement. Hitherto only the holders of degrees on the British register have been entitled to recognition in Italy; but in future the accession of India to the new agreement is to be provided for separately on a basis of equal reciprocity between Italy and India. We can serve no useful purpose meanwhile by approaching any authority in Italy.

From the other countries I mentioned the replies, in cases where the correspondence has been completed, have been, as I indicated at our last session, usually on the lines that they will recognize only those of our degrees that have received the recognition of the General Medical Council. I wish you earnestly to consider this matter and its implications, because you will be required to give a decision thereon at our next meeting. Unless you specifically recommend to the Governor-General that degrees which are not on our Second Schedule should remain thereon they will automatically be removed after next October. If you allow the degrees of one of the countries I have mentioned who are prepared to recognize our approved qualifications only *via* the General Medical Council to be removed from our Schedules the position would arise that graduates of Indian universities would be recognized in that country, but their graduates would not be recognized in India. At your next meeting you should have before you the recommendations of the executive committee on this subject and a précis of the replies from the countries concerned.

Most of the countries not on our Second Schedule with whom we have corresponded have no degrees of their own or at least no qualifications generally recognized; but they are of interest to us because Indian practitioners sometimes go there. They are Kenya, Tanganyika, Uganda, Zanzibar, British Guiana, Mauritius, Fiji, Iraq and Iran. Where correspondence has been concluded the replies vary from an inability to recognize anything not recognized by the General Medical Council to an acceptance in one case,

Tanganyika, of the degrees included in our First Schedule and approved by this council.

With both Iraq and Iran the position is different, but I should not detain you now to describe the peculiarities of these individual countries.

Our proceedings for the engagement of a new secretary to the council from next November have been the subject of correspondence with the Government of India, and this matter will come before you to-day as a separate item.

This is the last session of this council at which I shall have the honour to preside and the last occasion at which I shall have the opportunity of meeting many of the members of this council. It is a matter of great satisfaction to me that this council has been able to do so much directly and indirectly, in the ways that I described at our last session, towards the objects for which the council was established and I thank you for your cordial co-operation in the work we have performed. I thank more particularly the members of our executive committee who have given freely their time and experience to the benefit of the council, and especially I thank our Secretary, Colonel Burke, for the careful way he has always prepared the matter for our deliberations, and his office staff for their able assistance at all times.

My successor as President for the next year will be Major-General Bradfield, an officer known already to several among you and one who has already had experience of provincial medical councils in two of the presidencies of India. I feel assured that you will accord to him the support you have so generously given me and you too may rest assured that my concern in this council and its work will not cease with my resignation therefrom, but I shall always follow the council's proceedings with eager interest and will be ready to assist the council's just ends if opportunity allows me to do so.

I thank you all and wish you good-bye, and that the Medical Council of India may flourish and achieve its objects.

REORGANIZATION OF INDIAN MEDICAL SERVICE COMPOSITION UNDER REFORMS

(From the *Statesman*, Friday, 26th March, 1937)

Delhi, 24th March.

THE *communiqué* dealing with the reorganization of the Indian Medical Service under the new Constitution has now been amplified.

'The main object of the scheme', it says, 'has been to reconcile, as far as possible, the natural and legitimate desire of the provinces to exercise complete autonomy in the field of medical and health administration and of ensuring that officers and families of the superior civil service have the standard type of medical attendance to which they are entitled.'

It adds that the fulfilment of two needs referred to above might in either case be held to derogate to some extent from complete autonomy of the provinces, but the provinces themselves cannot disclaim all interest in the requirements of defence forces, since the protection that they afford obviously extends to provinces as integral parts of India.

Nor can there be any constitutional objection to the maintenance of the civil branch of the I.M.S. on an all-India basis for the purpose of attendance on members of superior civil services and their families, seeing that it has been decided to maintain on the same basis the I.C.S. and Indian Police.

The attainment of the objects in view can be secured most efficiently and economically, from the view point of India as a whole, by continuing the existing medical services broadly on their present basis, and the possibility of unifying the military medical services in India, which have frequently been examined and as frequently rejected for practical reasons during the last 50 years, must be finally abandoned.

So long as the superior civil services in India contain a number of British officers and British personnel, it is not unreasonable that these officers and personnel, like Indian members of the services, should be provided with opportunities of securing medical attendance for themselves and their families from doctors belonging to their own race.

The acceptance of this principle involves continuation of British recruitment to the I.M.S. by the Secretary of State by whatever methods are calculated to produce the best recruits.

On the other hand, the extent of British recruitment should in future be based on the actual requirements indicated above and not on the predetermined ratio of British and Indian officers.

From the fact that large numbers of qualified Indian doctors in private practice are available in India, while there are very few British, it follows that the war reserve on which the Army is to rely for its increased requirements in war must be composed mainly of British officers.

The importance of maintaining a war reserve of Indian officers of the I.M.S. cannot be placed on quite the same plane of necessity, but it is desirable to have a small reserve of such officers in civil employ, who will possess military knowledge and training as a result of regular service in the Army.

If the result of these considerations is not to increase or even to decrease the present proportion of Indians in the I.M.S., it must be recognized that further Indianization of the medical service must be looked for, not so much within the I.M.S. itself as in provincial services by throwing open to the latter the appointments which are now reserved for the former.

There should be no compulsion, therefore, on the provinces to employ I.M.S. officers in excess of the small war reserve mentioned above, but it should be open to them to employ as many Indians as they wish of their own free choice, provided only that they will guarantee them sufficient security of tenure to avoid an embarrassing surplus being thrown back on the Army for absorption as a result of some sudden change of policy.

The extent to which the provinces of the future should be required to employ I.M.S. officers should be no more than are strictly required for these purposes, and the Government of India themselves should do what they can to reduce these numbers both by providing the fullest justifiable establishments for the Army in peace and also by contributing their legitimate quota to the war reserve from among I.M.S. officers under the central civil departments.

The circumstances in which the officers of the I.M.S. are employed by the Provincial Governments in future should be such as to give the provinces the greatest possible latitude of choice to encourage the officers chosen to identify themselves as closely as possible with the interests of the provinces which they are serving and to relieve the provinces as far as possible of the extra expenditure involved in employing officers on higher rates of pay than those which they find sufficient to attract recruits to their own medical services.

Subject to the observance of the foregoing requirements, the fullest possible use should be made of indigenous material in meeting the medical needs of the Army and the strictest care should be taken to safeguard the personal rights of all serving members of the I.M.S. and also to maintain the attractions of the service which possesses a distinguished record of past achievements to the benefit of India and of humanity at large, and which has contributed so largely to the prescription and maintenance of high standards of medical and health administration in this country.

The present I.M.S. cadre (actuals) is composed of 649 officers (386 British officers, 200 are in the military and 186 in the civil branch, respectively. Of the 263 Indian officers, 154 are in the military and 109 in the civil branch, respectively.

The composition anticipated after the reorganization of the I.M.S. cadre will be as follows: Total 584 officers

(386 British and 198 Indian). Of these 386 British officers, 220 will be in the military and 166 in the civil branch, respectively. Of the 198 Indian officers, 144 will be in the military and 54 in the civil branch, respectively.

The *communiqué* adds that, from what has already been said, it is obvious that the merits or demerits of the present scheme of reorganization must be judged not from any single point of view, but from a number of different angles.

The increase in the present authorized establishment of the officers on the Army side, although not restoring those establishments to the strength of those employed previous to the last retrenchment, will involve considerable increase of expenditure in the immediate future.

This additional expenditure will be further increased by the necessity of providing conditions for the existing members of the I.M.S. so as to maintain a proper balance between the attractions of that service and the Royal Army Medical Corps and by the acceptance of liability to pay the provinces a subsidy in respect of 77 British I.M.S. officers of the war reserve who will be employed by them.

On the other hand, the Government of India are satisfied that the reorganization will provide adequately for the requirements of the Army both in peace and war and also for those of the Crown representative, the civil departments of the Central Government and members of the superior civil services and their families.

Considerable savings will ultimately result both under the pay and pension charges in the Defence Budget.

It is estimated that the financial effect of the reorganization on the Defence Budget during the next few years, even after the separation of Burma has been taken into account, will be an increase of about Rs. 50,000 under effective pay charges and about Rs. 3½ lakhs by way of subsidy to the provinces in India, but that ultimately the cost of the larger number of officers to be employed will be several lakhs less than the present charges.

Although for a period the provinces will continue to employ and pay at the present rates a number of British and Indian I.M.S. officers who possess personal rights in addition to the 160 referred to above, those of them which employ war reserve officers will be relieved with effect from 1st April, 1937, of the average cost of overseas pay of 77 British officers who will constitute the statutory war reserve in the provinces.

The terms of cash relief will vary from about Rs. 65,000 yearly for the largest provinces down to about Rs. 15,000 yearly for the smallest.

The provisions by which the provinces will be authorized to exercise the maximum discretion with minimum intervention from the Central Government in initial selection, ultimate retention and interchange of officers to be employed, combined with provisions by which officers themselves will forego the right to revert to the Army after a suitable period of civil employment, will tend to promote that community of interest between the employer and the employed which is essential to the smooth and efficient working of all administrative arrangements.

Short-service commissions

An improved time scale of promotion and revised scales of pay for present incumbents combined with a re-adjustment of scales of basic and overseas pay for future entrants should provide for British and Indian officers alike inducements required to enable the service as a whole to compete successfully for recruits of good quality with what may be described as its principal rivals.

To a British officer, that is to say, the I.M.S. will provide attractions in many respects superior to those of the R.A.M.C. To an Indian officer it will offer better terms than any provincial medical service.

The method of entry by selection and nomination which has given good results in the past will be continued, but the introduction of short-service commissions for Indians on the model of the R.A.M.C. system should eliminate the criticism now directed against the

present system of granting temporary commissions for one year at a time up to a total of five years.

The resolution of the Government of India (Defence Department) with the approval of the Secretary of State contains changes that will be made in the organization, distribution and terms of service of military medical services in India (excluding Burma). Where necessary rules giving effect to these proposals will be made by the Secretary of State under Part X of the Government of India Act, 1935.

While recruitment for the I.M.S. will continue as at present to be conducted by nomination on recommendation of the Selection Board, the normal method of entry for Indian members of the service will follow the system adopted in the R.A.M.C. New entrants will be given short-service commissions for five years. The present temporary commissions renewable from year to year up to five years will be abolished, but the present holders of temporary commissions will be eligible for selection for the grant of short-service commissions and ultimately of permanent commissions on prescribed terms, that is to say, after a total of five years of service in a non-permanent capacity.

For a period of two years, from 1st April in order to give sufficient notice of change, the Secretary of State will reserve the right to appoint suitable Indian candidates permanently to the service without the preliminary of short-service commission.

Special pensions

While liability to serve either on military or civil side has for many years been a recognized condition of service in the I.M.S., it has been made clear since March 1931 that no new entrant to the service since that date can establish any claim to be transferred to civil employment.

Subject to the maintenance of these general conditions, the terms on which I.M.S. officers will be transferred to civil employment after 1st April will be revised.

The Director-General of the I.M.S. will endeavour to come to a working agreement with all civil employers under which the latter will intimate at periodical intervals their probable requirements for the next six months.

A suitable number of special pensions equal to a colonel's pension will be provided for award to selected officers (in civil employment) on the special supernumerary list in order to compensate for the loss of pensionary prospects that would otherwise be involved by ineligibility for promotion above the rank of a lieutenant-colonel.

Reserved appointments

Three appendices classify reserved I.M.S. appointments under the Central Government and Provincial Governments, as also rates of pay for present and future entrants.

The present basic pay of a lieutenant will be Rs. 500 plus an overseas pay of Rs. 150 per mensem and for a captain Rs. 650 up to a maximum of Rs. 850 plus an overseas pay of Rs. 150 and £30, respectively.

For a major a minimum of Rs. 950 plus £30 overseas and maximum Rs. 1,250 plus £30.

For a lieutenant-colonel Rs. 1,500 plus £30 and Rs. 1,600 plus £30.

For future entrants the basic pay for a lieutenant will be Rs. 450 plus £15, for a captain minimum Rs. 500 plus £25, maximum Rs. 700 plus £35, for a major Rs. 800 plus £35 and Rs. 1,100 plus £40 and for a lieutenant-colonel minimum Rs. 1,350 plus £40, maximum Rs. 1,500 plus £40.

BOMBAY MEDICAL COUNCIL

The following extracts from a summary of the proceedings of the meeting of the Bombay Medical Council held on 1st February, 1937, are published for information:—

The council proceeded to consider the requests made by the representatives of newspapers and certain

visitors at the meetings of the council for the supply to them of the papers connected with the agenda and resolved that it is not practicable to furnish copies of such papers to the press or the visitors.

The council proceeded to consider further the application of Mr. G. S. Kasyapi, L.M. & S., for the restoration of his name to the Bombay Medical Register and resolved that sufficient time had not yet elapsed before his request could be entertained.

The council proceeded to consider the application of Mr. Shripad Narhar Kulkarni, M.B., B.S., for the restoration of his name to the Bombay Medical Register and resolved that his name be restored to the register.

The council proceeded to consider further the draft revised code of medical ethics and resolved (i) that it is not desirable to issue any binding rules or to insist on a rigid code which shall have the force of law but that full freedom should be retained to treat any case on its merits and (ii) that further elaboration of the ethical principles which should guide members of the profession is not necessary.

The council proceeded to consider further the reference from the Medical Council of India regarding the conditions of medical practice in the French Establishments in India affecting Indian Nationals possessing medical degrees included in the First Schedule to the Indian Medical Council Act, 1933, and resolved to endorse and agree with the resolution passed by the Madras Medical Council at their meeting held on 27th October, 1936, viz, that 'This (the Madras Medical Council) resolves to request the Medical Council of India immediately to recommend to the Government of India to correspond with the French Government in order that registered medical practitioners in the provincial registers in this country may be allowed to practise in French India, and in case the French Government refuses to comply with this suggestion, that the Government of India may be requested by the Medical Council of India to enact suitable legislation to prevent practitioners from French India from practising in British India unless they are in the provincial registers'.

The council proceeded to consider the reference from the Medical Council of India regarding the conditions of medical practice in Portuguese India affecting Indian Nationals possessing medical degrees included in the First Schedule to the Indian Medical Council Act, 1933, and resolved (i) that no further action in the matter appears called for, as the reciprocity at present existing between the Government of Bombay and the Government of Portuguese India has been continued, but (ii) that the Medical Council of India should be informed that the Bombay Medical Council would urge that the Government of Portuguese India be requested to allow all medical practitioners registered under the Bombay Medical Act, VI of 1912, to practise in Portuguese India.

The council proceeded to consider the request of the Dean, the Nair Hospital Dental College, Bombay, for the council's support in bringing a Dentists' Registration Act on the Statute Book and resolved that the council would be prepared to assist in the preparation of a Dentists' Registration Act for Bombay, if a demand for such an Act is made by an organized dental profession.

The council proceeded to ballot for the election of an executive committee for the year and, in accordance with the result of the ballot, declared the following six members as duly elected:—

Dr. D. A. D'Monte, Dr. Rajabally V. Patel, Sir Mangaldas V. Mehta, Lieut.-Col. W. C. Spackman, Lieut.-Col. Sir Bahadur Sir Nasarvanji Choksy, and Lieut.-Col. Sir Jamshedji N. Duggan.

The council proceeded to consider certain points raised by the registrar for orders in connection with the next general elections of members of the council, due to be held during the year, and resolved that—

- (i) the existing practice of treating the Medical Register as the electoral roll under clause (1) of Rule 12 of the Rules of the Council be continued;

- (ii) all practitioners registered up to the 10th August, 1937, should be included in the electoral roll;
- (iii) 12th August, 1937, should be fixed as the date up to which nomination papers should be received in the council's office;
- (iv) 19th August, 1937, should be fixed as the date for the issue of voting papers;
- (v) 10th September, 1937, should be fixed as the latest date for the return of the voting papers and the counting of votes; and
- (vi) that the various instructions required to be published should be published in the *Bombay Government Gazette*, the *Times of India*, the *Bombay Samachar*, the *Daily Gazette*, Karachi, the *Kesari*, Poona, and the *Sind Official Gazette*, and through all Medical Associations and societies on the list of the Office of the Council.

The council proceeded to consider a motion given notice of and made by Mr. R. A. Amesur and seconded by Dr. P. T. Patel and supported by Mr. M. N. Talati, proposing the amendment of Sections 2, 5 and 19 of the Bombay Medical Act, VI of 1912, and the motion was lost, a majority of the members voting against it.

The council proceeded to consider a motion by Mr. M. N. Talati, regarding the grant of fees and travelling allowance to the members for attending the meetings of the council and the committee, but the motion fell through for want of a seconder.

The present meeting being the last on which Major-General Bradfield had to preside in view of his impending departure to take up the appointment of his Director-General, Indian Medical Service, Sir Temulji Nariman then moved—

That the council place on record their appreciation of the cordial way in which General Bradfield had always conducted the meetings of the council and the great help he had rendered in the disposal of the business which came before them.

The motion was seconded by Sir Nasarvanji Choksy and on being put to the vote, was carried unanimously. After General Bradfield had made a suitable reply and thanked the members, the meeting terminated.

THE TINNEVELLY DISTRICT MEDICAL ASSOCIATION, PALAMCOTTAH

(AFFILIATED TO THE INDIAN MEDICAL ASSOCIATION)

The Tinnevely District Medical Association held its monthly meeting on Saturday, 27th February, 1937. In the morning a health exhibition was arranged at the Board High School, Nanguneri. The exhibition was opened by Lieut.-Col. T. S. Shastri, I.M.S., the president of the Association. The exhibition was kept open to the public till late in the evening. The exhibits consisted of posters relating to cholera, tuberculosis, malaria, smallpox, fly-danger, etc. About 300 school teachers and school mistresses of Nanguneri taluk attended the health exhibition which was held at the same place and along with the educational exhibition of the Elementary School Teachers' Conference. Leaflets on venereal diseases kindly supplied by the National Health Association of Southern India, Madras, were distributed to all of the teachers, mistresses, etc.

The monthly meeting of the association was held at 4-30 p.m. with tea and music on the Veena at the Traveller's Bungalow, Nanguneri, under the presidency of Lieut.-Col. T. S. Shastri, I.M.S. Thirty members of the association were present on the occasion. The following resolution regarding the demise of Diwan Bahadur Dr. C. Natesa Mudaliar, L.M. & S., was passed unanimously:—

'The Tinnevely District Medical Association places on record their sorrow at the demise of Diwan Bahadur Dr. C. Natesa Mudaliar, L.M. & S., M.L.C., one of the most prominent and respected members of our profession who did silent and loving service to the sick poor, and one of the most useful citizens of our Presidency, and conveyed to the bereaved family their heartfelt sympathy'.

The secretary and treasurer, Dr. K. Rama Ayyar, M.B.B.S. (Andhra), read the minutes of the Eighth

Anniversary of the Tinnevely District Medical Association, which were passed.

The following interesting specimen was shown to the members:—

By whom	Specimen
Lieut.-Col. T. S. Shastri, I.M.S.	Dermoid cyst (left ovary) with balls of hair.

The following interesting cases were demonstrated:—

By whom	Cases
Lieut.-Col. T. S. Shastri, I.M.S. Dr. M. Vaithianathan, L.M.P. Dr. G. S. Narayana Iyer, L.M.P.	Syphilitic gastritis Tuberculous peritonitis. Aphasia (chronic).

Dr. P. S. Srinivasan, L.M.P., sub-assistant surgeon of the Government Headquarters Hospital, Palamcottah, read out the following interesting cases:—

(a) Myxœdema and cretinism (in one and the same family), (b) strangulated hernia with a tumour on the pelvic colon, (c) syphilitic gastritis, and (d) an early case of mycetoma of the foot. Dr. M. Vaithianathan of Nanguneri read the clinical notes of a case of tuberculous peritonitis. Dr. G. S. Narayana Iyer read out his notes of the case of aphasia.

After detailed discussion by the members, Lieut.-Col. T. S. Shastri, I.M.S., summed up the salient and important features of all the cases. He offered his cordial thanks to all those members who helped towards the success of the function and thanked Dr. M. Vaithianathan for the excellent arrangements.

HUNTERIAN SOCIETY

GOLD MEDAL FOR PRACTITIONERS

ANY registered general practitioner resident within the British Empire is eligible to compete, and the medal, which is of gold, is awarded annually to the writer of the best essay on a subject selected by the Society.

Competitors—men or women—must be engaged in general practice and essays should be sent in by 31st December.

The essay must be unpublished and original, and be based on the candidate's own observation, but it may contain excerpts from the literature on the subject, provided that reference be made to the articles from which they are taken.

A copy of the rules and any further information can be obtained on application to the honorary secretary, Mr. Arthur E. Porritt, 27, Harley Street, W.1.

The subject selected for the essay is:—

1937—'The prognosis and care of heart disease in general practice'.

1938—'The management of inoperable malignant disease in general practice'.

The 1936 Hunterian Gold Medal for practitioners was won by Dr. L. J. A. Parr, of Sydney, Australia, for his essay on 'Rheumatoid arthritis'.

COLLEGE OF PHYSICIANS AND SURGEONS OF BOMBAY

THE council of the College of Physicians and Surgeons of Bombay at their meeting held in January 1937 decided to institute an examination for the diploma in ophthalmic medicine and surgery and appointed a committee to draw up regulations and syllabus of study for that examination.

The committee submitted its report to the council at their meeting held on the 12th March, 1937, when it was resolved that the report be approved and

adopted; and that the first examination for the diploma in ophthalmic medicine and surgery be held in July 1937.

Regulations relating to the examination for the diploma in ophthalmic medicine and surgery

The College of Physicians and Surgeons of Bombay shall grant a diploma in ophthalmic medicine and surgery (D.O.M.S.).

2. The seal of the college shall be affixed to every diploma.

3. The examination shall be held annually in Bombay on the last Monday in July.

4. The examination shall be open to all those registered with the Bombay Medical Council*.

5. Candidates must apply to the secretary of the college for permission to appear at the examination at least two weeks before the date of commencement of the examination, and shall at the same time pay a fee of Rs. 100. Fees once paid shall not be refunded, but may be reserved for the subsequent examination only at the discretion of the college council, provided that the application for such reservation is made at least seven days before the date of the commencement of the examination, and good and sufficient reason is shown for the same. A candidate who fails to pass or to present himself at an examination may be admitted to one or more subsequent examinations on a fresh application being made and a fresh fee being paid.

6. No candidate will be admitted to the examination unless he produces the following certificates—

(a) Of having attended as a post-graduate for a period of nine months the clinical practice of an ophthalmic hospital or the ophthalmic department of a general hospital (having at least 20 ophthalmic beds) recognized by the College of Physicians and Surgeons.

The conditions of this certificate will be fulfilled by holding an appointment as house surgeon or house physician or as clinical assistant or as post-graduate at one of the recognized ophthalmic hospitals or ophthalmic department of a general hospital.

(b) Of having attended the following courses for a period of three months at an institution recognized by this college for the purposes of the M.C.P.S. examination:—

- (i) a course of study in optics;
- (ii) a course of study in the anatomy and physiology of the eye;
- (iii) a course of study in pathology and bacteriology with special reference to ophthalmic medicine and surgery; and
- (iv) a course of ophthalmic operative surgery.

7. The examination shall be written, practical, clinical and oral. There shall be four papers, each of three hours' duration, and each carrying 100 marks in each of the following subjects:—

- (a) Anatomy and physiology of the eye and optics;
- (b) Bacteriology and pathology of the eye;
- (c) Ophthalmic medicine and surgery; and
- (d) Relation of ophthalmology to general medicine.

There shall be practical, clinical and oral tests, carrying 400 marks as under:—

- | | |
|--|-----|
| (i) Clinical examination | 100 |
| (ii) Dark-room examination | 100 |
| (iii) Pathological specimens of the eyeball and microscopic slides | 100 |
| (iv) Ophthalmic instruments, appliances and viva voce | 100 |

8. To pass the examination, the candidate must obtain 40 per cent of the full marks in each paper, 50 per cent of the full marks in the practical, clinical and oral tests; and 50 per cent of the full marks in the

* A candidate shall at the time of applying for permission to appear at the examination produce a certificate stating that he is registered with the Bombay Medical Council.

written, practical, clinical and oral tests taken together.

9. The subjects for study shall be—
 - (a) Anatomy and embryology of the eye, including the contents of the orbit, bones in relation thereof and the central nervous system as far as it relates to the eye;
 - (b) Physiology of vision;
 - (c) Physiological optics;
 - (d) Errors of refraction;
 - (e) Ophthalmic medicine and surgery;
 - (f) Pathology and bacteriology of the eye;
 - (g) Relation of ophthalmology to general medicine; and
 - (h) Operative surgery.
10. Every person before receiving his diploma in ophthalmic medicine and surgery shall make and sign the following declaration:—
 'I.....do solemnly and sincerely declare that, while holding the diploma of the College of Physicians and Surgeons of Bombay, I will obey every lawful order of the council of the College, and that I will demean myself honourably in the practice of my profession, and to the utmost of my power maintain the dignity and honour of the College'.

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

The following students are declared to have passed the D.T.M. examination, session 1936-37.

1. Pashupati Bose, M.B. (Cal.), assistant surgeon, Government of Bengal—awarded the 'Chuni Lal Bose' Gold Medal, 1937.

Passed

- (Arranged in alphabetical order)
2. Amar Singh, L.S.M.F. (Agra), I.M.D., sub-assistant surgeon, Government of India.
3. Bachan Singh, L.M.P. (Agra), I.M.D., sub-assistant surgeon, Government of India.

4. Balwant Singh Banda, L.S.M.F. (Punjab), I.M.D., sub-assistant surgeon, Government of India.
5. Ajit Kumar Basu, M.B. (Cal.), private practitioner.
6. Lal Mohan Bhattacharjee, M.B. (Cal.), private practitioner.

Current Topics

Gonococcus Filtrate (Corbus Ferry) Pædiatrics

By A. B. LeBEL
(From *L'Union Médicale*, October 1936)

VULVO-VAGINITIS of a gonococcal nature presents itself often in baby girls of various ages. The onset of the disease is always the result of contagion and becomes highly contagious. In new born the infection may pass unnoticed for some time. Later on, an abundant and purulent discharge from the vagina is found on the diapers. Local examination reveals a pronounced redness, vulvar discharge, itching, erythema which in some cases is very intense. Very soon after this acute stage the infection becomes chronic and may remain so for a very long time; in fact, chronic vulvitis is considered a very serious disease because of its tenacity and strong resistance to treatment.

Early in 1935, my attention was called to some findings made in the nursery at L'Aide a la Femme. Some of the little girls in a ward had a vulvo-vaginal discharge. It was of a yellow-greenish tint, thick, glazy, producing a starched effect on the diapers and causing adherence of the outer lips. I immediately realized that we were in the presence of an acute form of gonococcal vulvo-vaginitis. Bacteriological reports confirmed this.

Many of the little patients were contaminated by close contact in the ward. The epidemic was checked by isolation and very careful sterilization of clothing and diapers. The original cause of this infection could

not be determined but I believe it was brought in by some young patient harbouring the disease in the incubation stage.

At the very start the following treatment was established: Twice a day careful cleansing of the vulva and external region with a 0.25/1,000 solution of potassium permanganate, followed by a vaginal douche with the same solution. At night a 5 per cent silvol bougie was introduced in the vagina.

Serious difficulties are often met in this form of treatment, because of the diseased organs not having obtained their full maturity in these young patients. This treatment did produce sensible improvement for a certain period, but a slight discharge returned as soon as local treatment was discontinued. Remissions and recrudescences occurred even when the above treatment was scrupulously followed and the end of this infection seemed to me very far away. Comby reported on a little girl with such an infection of two years' duration.

Complications are not the usual rule, yet gonorrhoeal ophthalmia may be caused by pus being carried to the eyes by the child. Other complications are also to be feared, such as Bartholinitis, ano-rectal gonorrhoea, metritis, salpingitis, ovaritis. Cheadle even observed a pyosalpingitis in a 21-months-old girl. Baginsky found pus in the ovaries.

Fisher reports that Bartholin's glands are involved in one-third of his cases. Eraud claims that the cervical canal is always involved in vulvo-vaginitis.

Because of the severity of the lesions caused by the organs of these little patients and the tendency the disease has to chronicity, I was prepared to fight the

infection in different ways, and was glad to accept the suggestion made to me by Dr. G. Brisebois, of Parke, Davis and Co., to try the Corbus-Ferry gonococcus filtrate. This product was used concurrently with theelin in oil 2,000 units per cubic centimetre.

This new treatment was started on 14th December, 1935. Each child received 1/40 c.cm. of gonococcus filtrate once a week for eight weeks. Parke-Davis theelin in oil was given in doses of 1/10 c.cm. at two-day intervals for five injections.

The second injection of theelin produced an exaggerated discharge which disappeared in 48 to 60 hours. This was more pronounced in patients with a more intense infection. After the last or fifth injection of theelin the discharge had almost completely disappeared and at the fourth injection of gonococcus

filtrate no discharge could be found. The local reaction following intradermal injections of the diluted filtrate was slight except in two patients who had a very deep infection. These gave marked cutaneous reactions. No rise in temperature was noted.

During the six months' period, preceding the filtrate treatment, the microscopic reports alternated from positive to negative and from negative to positive. At the end of the treatment with the gonococcus filtrate and since then all reports have been negative.

Dr. Georges Luys, in his treatise *La Blennorrhagie*, states: 'Very often these little girls are not properly treated and at a much later period in their life it is not infrequent to find the gonococcus in the secretions of these innocent victims of a far back infection of obscure origin'.

Reviews

MODERN UROLOGY. In original Contributions by American Authors. Edited by Hugh Cabot, M.D., LL.D., C.M.G., F.A.C.S. 1936. Volumes I and II. Third Edition. 1936. Henry Kimpton, London. **Volume I:—General Considerations, Diseases of Penis and Urethra, Diseases of Scrotum and Testicle, Disease of Prostate and Seminal Vesicles.** Pp. 951. Illustrated with 546 engravings and 12 plates. **Volume II:—Diseases of the Bladder, Diseases of the Ureter, Diseases of the Kidney, Radiation Therapy of Tumours of the Genito-Urinary Tract.** Pp. 862. Illustrated with 374 engravings and 9 plates. Price, £4 10s. for the two volumes

If there should be a doubt in the mind of any doctor as to the important place urology has taken in the curriculum of surgery, he has only to consult a catalogue and count the large number of books, great and small, which have been written on this subject during the last decade.

The work under review, *Modern Urology*, is not only one of the latest additions to this section of the surgical library, but it is one of the most monumental, and most useful.

The work is divided into two volumes. The first being written by 22 contributors and dealing with general conditions. Diseases of the penis, urethra, scrotum, testicle, prostate and seminal vesicles. The second deals with diseases of the bladder, ureter, kidney, and ends with a consideration of radiation therapy of tumours of the genito-urinary tract. This volume has 16 contributors.

The work opens with an historical survey of the subject of urology and an interesting description of the evolution of the cystoscope, and all the modern methods of teaching in America—the use of the phantom bladder for teaching purposes being insisted upon in all the great schools.

Great stress is laid upon the proper preparation of the patient for urological examination, especially for that of cystoscopy. The contributor states, 'Even in the hands of the most dexterous operator this simple procedure is often accompanied by considerable pain'; and he goes on to say that it is this avoidable pain which has given cystoscopy its unenviable reputation. The pain can easily be obviated by the instillation of 4 per cent novocain. This is in great contradistinction to the thought of the French urologists who maintain that the anæsthetic is in the fingers of the operator.

The whole work is so big and so good that it is extremely difficult to single out passages for special mention, but the section on the prostate must be especially called to the notice of the reader. This subject is magnificently dealt with, and all the operations for relief of senile hypertrophy of the prostate are carefully described and contrasted, a special chapter being devoted to trans-urethral resection.

The writer of the section on gonorrhœa pleads for conservative methods of treatment of this disease, and deprecates the indiscriminate use of the many 'remedies' for this condition which are continuously being put upon the market.

Diseases of the kidney and a treatise on calculi of the urinary tract are dealt with in the last few chapters, and the second volume ends with a consideration of the treatment of genito-urinary tumours by radiation therapy. If we may make one small criticism, it is that we are somewhat surprised to note that the use of mandelic acid compounds in the treatment of cystitis is merely mentioned once, and dismissed in one line. As this drug has been found by recent observers to be of the greatest value in cystitis, especially when due to the *Bacillus coli*, it is certain that future editions of *Modern Urology* will contain a more elaborate description of its use.

This work must be considered one of the great standard books of reference on urology, containing as it does all modern thought on this subject. It has been compiled with the greatest of care and attention to detail. The printing is good, the phraseology easy to read, the illustrations, plates and diagrams excellent, and the bibliography considerable.

The editor and the contributors are to be congratulated in having produced a work of the utmost value.

H. E. M.

RECENT ADVANCES IN ANÆSTHESIA AND ANALGESIA (INCLUDING OXYGEN THERAPY).—By C. L. Hewer, M.B., B.S. (Lond.), D.A. (R.C.P. & S. Eng.). Second Edition. 1937. J. and A. Churchill, Limited, London. Pp. x plus 284, with 113 illustrations. Price, 15s.

THE publication of the second edition, after an interval of five years, requires no apology and comes, in fact, at an opportune moment. With all the progress of anæsthesia in view, the author has dealt with the subject in the right way and produced just what is wanted and the book will prove of real value to all who are interested in this branch.

The theoretical aspect of anæsthesia is described, but the book is mainly devoted to the practical side. The chapter on biochemistry is excellent and will be useful not only to the surgeon and the anæsthetist, but also to the research worker.

The administration of anæsthesia has long been regarded as an art rather than a science, and there is little doubt that art—or more correctly judgment—still plays an important part in it. Nevertheless investigation of the many factors concerned in anæsthesia increases year by year and the modern trend is towards a scientific basis. It is no exaggeration to state that research has already been justified by the results and it is not too much to expect further advances.

The quest of improvement has, however, produced a multiplication of anæsthetic agents and methods which are bewildering, and, to add to the perplexity of situation, there is a divergence of opinion among experts as to which of these is the best. The author fulfils more aims than one; he succeeds in enabling us to sift the advantages and indications for each agent and the method to be used. Mindful of the requirements of the general practitioner he has not neglected to emphasize the value of chloroform and ether, and details are given of the administration of these agents. The chapter on shock is one calculated to be of value to the surgeon as well as to the anæsthetist, since the cause of this condition does not always seem to be fully appreciated. Finally, there is apparent, throughout the book, a clear conception of the physiological requirement and reactions of the patients, without which competence in the art of anæsthesia cannot be attained. Oxygen therapy is not a branch of anæsthesia, but its inclusion is justifiable as it embodies many of the same principles, is administered with similar apparatus and has largely been developed by anæsthetists. The format is excellent, the illustrations are clear and well selected. The book represents one of the really valuable contributions to medical literature.

R. N. C.

BRIGHT'S DISEASE AND ARTERIAL HYPERTENSION.—By Willard J. Stone, B.Sc., M.D., F.A.C.P. 1936. W. B. Saunders Company, Philadelphia and London. Pp. xiv plus 352. Illustrated. Price, 22s. 6d.

The volume contains a critical survey of Bright's disease and deals with its clinical features and treatment. In it the author has referred to many of the better-known recent publications and is up to date. He emphasizes the inadequacy of the previous forms of classification and leans towards the conception that nephrosis is a part of a general metabolic disturbance in which the kidneys show only a phase. His classification agrees with that of Addison with obvious affinities and he divides Bright's disease into hæmorrhagic and degenerative types, the former passing to stage of chronic arterio-sclerotic kidney with primary hypertension, subdividing this into latent and active types. The author considers that arterio-sclerosis with renal manifestation can best be explained by assuming that arteriolar involvement antedates the renal changes and that nephritis is either a result of the vascular changes or due to the same cause which produces an abnormal condition of the arterioles.

In the first few chapters the author deals with the physiological, pathological and biochemical aspects of the problem and the various types of nephritis are separately described with advice on treatment. The work is in general sound and conforms to the advanced line of teaching. The book is profusely illustrated and contains some beautiful microphotographs. On page 121, the author has described a simple test for blood which he claims will enable the detection of approximately 1,300 blood cells per cubic centimetre of urine. This sensitive test deserves attention in view of the great clinical importance.

The book is nicely got up and will certainly prove useful to the medical profession and the author should be congratulated on his painstaking and difficult task.

R. N. C.

A MANUAL OF PHARMACOLOGY AND ITS APPLICATIONS TO THERAPEUTICS AND TOXICOLOGY.—By T. Sollmann, M.D. Fifth Edition. 1936. W. B. Saunders Company, Philadelphia and London. Pp. 1190. Illustrated. Price, 32s. 6d.

PROFESSOR SOLLMANN'S *Manual of Pharmacology* is too well known to need any introduction from us and a new edition is sure to be welcome. A great demand of this important treatise has no doubt necessitated another edition in such a short period since the publication of

its previous edition in 1934. The dominant object of this manual, as Professor Sollmann says, is to furnish medical students and interested practitioners with an outline of the current conceptions of the actions of drugs, especially from the point of view of their practical importance in medicine. Unless one knows how a drug acts and its various actions on the different systems of the human body, one cannot possibly make its application in diseases, and this practical aspect of drugs has been well brought forward by Professor Sollmann.

The book has been brought thoroughly up to date, keeping abreast of all the recent development in the domains of pharmacology and therapeutics. The incorporation of the latest researches into endocrine therapy, particularly of the sex hormones, their latest nomenclatures and interrelations with other hormones, especially with those of the anterior pituitary, the vitamins, the new ergot principle ergometrine, the cyanide antidotes, dinitrophenol, neurohormones, cyclopropane, etc., have undoubtedly enriched the manual further.

The publishers are to be congratulated for the excellent get-up of the book. The inclusion of a complete bibliography at the end of the book has made the treatise more useful and valuable for the research worker and the practitioner alike and, hence, it might be considered more as a reference book than an ordinary textbook for students. The book should make a wide appeal to the medical profession at large.

HAY FEVER WITH SPECIAL REFERENCE TO TREATMENT BY INTRANASAL IONIZATION.—By Clive Shields, B.M., B.Ch. (Oxon.). 1937. Oxford University Press, London. Humphrey Milford. Pp. 57. Illustrated. Price, 7s. 6d. Obtainable from Oxford University Press, Bombay, India

In this small book the anatomy, physiology and histopathology of the nose and paranasal sinuses are considered in some detail. This is followed by a detailed description of the author's technique of intranasal zinc ionization for the treatment of hay fever. Although this method of treatment has been in use for the last twenty-five years, it is not known how zinc ionization acts. In the absence of any satisfactory explanation the author has advanced a tentative theory; 'that in allergic nasal conditions, there is a local ionic imbalance, content of the tissue of the nose'. This leads to increased secretion and hypersensitivity of the nasal mucosa. Treatment by intranasal zinc ionization results in the hypersensitive mucosa being rendered less sensitive by the application of a coating of zinc albuminate to the lining membrane and an impregnation of the cells constituting that membrane with the same substance. 'Proper ionic balance can then be restored by the defence mechanisms of the body.' This hypothesis to explain the rationale of the treatment is not supported at all by any clinical or experimental evidence.

D.

A TEXTBOOK OF PATHOLOGY.—By W. G. MacCallum. Sixth Edition. 1936. W. B. Saunders Company, Limited, Philadelphia and London. Pp. xvi plus 1277, with 697 illustrations. Price, 42s.

As a textbook of pathology the popularity of this book is well deserved and is reflected in the production of six editions within two decades. The general arrangement of this edition follows the plan of its predecessors and the text has been thoroughly revised. The chapters on inflammation and nephritis incorporate the newer ideas of cellular mobilization. The chapters on specific infections are exhaustive and up to date, especially those dealing with bacterial infections. A new chapter has been added on mycotic diseases. Considerable additions have been made in the chapters dealing with spirochætal infections and virus diseases and the section on diseases of the endocrine glands has been thoroughly revised in the light of recent work on

the subject. A new chapter on diseases affecting teeth and related structures has been added. The illustrations of which there are many are admirable, carefully chosen and well reproduced.

This new edition worthily maintains the high standard of this well-known textbook and there cannot be any hesitation in very strongly recommending this book to students and practitioners of medicine.

C. L. P.

SURGICAL ANATOMY.—By Grant Massie, M.B., M.S. (Lond.), F.R.C.S. (Eng.). Third Edition. 1937. J. and A. Churchill, Limited, London. Pp. x plus 468, with 153 illustrations, many in colour. Price, 18s.

GRANT MASSIE'S *Surgical Anatomy* has just gone through its third edition. The text has been carefully revised and various additions and alterations have also been made. As in the previous editions, every endeavour has been made to strike a balance between the anatomical and surgical matter, which in itself is a creditable achievement.

The book consists of six parts, the first dealing with the head and neck. The standard routes of surgical approach to the cranial contents have been clearly explained. The next part has been devoted to the upper limb. The section on the abdomen and pelvis is full of interest. Particular mention may be made of the surgical anatomy of the stomach, the biliary tracts, and the rectum. The remaining chapters deal with the lower extremity, thorax and the vertebral column. The arrangement and distribution of the autonomic nervous system have been effectively described.

The present volume is a member of Churchill's well-known Empire Series and its popularity is well merited. The printing, get-up and illustrations are excellent. We have much pleasure in recommending it for senior medical students and their teachers.

P. N. R.

PATHOLOGY. PARTS III AND IV.—Revised by J. Miller, M.D., F.R.C.P.E. Fourth Edition. (Catechism Series.) 1936. E. and S. Livingstone, Edinburgh. Pp. from 153 to 308. Illustrated. Price, 1s. 6d. each part. Postage, 2d. each part

PART III deals with diseases of the vessels, ductless glands, spleen, lymphatic system, heart and of the blood. Part IV deals with inflammation, infection, fever, repair, immunity and with diseases of the bronchi and lungs. Each of the subjects is dealt with in a concise and clear manner, so characteristic of the publications in the Catechism Series.

The presentation of the subject-matter in five volumes will be found particularly valuable to the student. These books are well suited to the purpose for which they are intended.

C. L. P.

AIDS TO PATHOLOGY.—By H. Campbell, M.D., F.R.C.P., and K. Campbell, O.B.E., M.B., F.R.C.S. Seventh Edition. 1936. Baillière, Tindall and Cox, London. Pp. viii plus 263. Illustrated. Price, 4s. 6d.

THIS very popular member of the Students' Aids Series has passed through seven editions and six reprints since it was first published in 1907. The present edition has been revised throughout, and many of the chapters have been rewritten, bringing the whole subject matter up to date. For a student who has completed a course of pathology and who wishes to revise rapidly the subject, or a busy practitioner who wishes merely to refresh his memory on certain points, this volume has many advantages.

C. L. P.

THE TRUE NATURE OF VIRUSES.—By W. M. Crofton, M.D. 1936. John Bale, Sons and Danielsson, Limited, London. Pp. xvi plus 139. Illustrated. Price, 15s.

In the introduction the author states that he has attempted to prove (1) that microbes acknowledged as the cause of a disease such as the tubercle bacillus break up into a filterable-virus phase which reproduces the disease, (2) that such typical virus diseases as fowl-pox and smallpox have always associated with them microbes which transmit the disease to other animals, (3) that diseases such as distemper and influenza are caused by microbes invariably present and that the so-called viruses are virus phases of these microbes which have been proved pathogenic, (4) that sarcomata are produced by the filter-passing phases of streptothrices which can always be grown from them; the virus phases 'fertilizing' the nucleus and turning it into a malignant cell, (5) that virus phases of other microbes produce scleroses and other tissue changes generally called degenerations.

This indeed is an ambitious project, but a careful perusal of the book leaves a very distinct impression that the author is so influenced by his own theories that to quote his own words 'he has found it difficult to write with any scientific calmness'. He is so biased by his own hypotheses that any evidence which does not fit in with his own views is dismissed as due to the result of 'bacteriological incompetence'. Of the influenza bacillus the author writes, 'I have every reason to be satisfied with my original and unshakable judgment and my freely expressed contempt for any other conclusion both then and since. Anyone holding any other opinion about this bacillus I consider an incompetent observer whose opinion is unworthy of consideration, as a person incapable of being convinced by the evidence of proof'. This contempt for modern work on virus diseases is apparent throughout the book and colours the presentation of the author's own work and theories.

The main theme of Dr. Crofton's work is that the so-called viruses are stages in the life cycle of certain bacteria and that these bacteria should be used for the production of immunity and not the viruses themselves. With vaccines made from these bacilli the author records the most astounding cures, results obtained in the course of a few hours, to quote but one case of delusional insanity who two hours after the administration of a one-million dose of influenza bacillus antigen sat down to dinner apparently perfectly sane. The author states that the result had to be seen to be believed. Although we are perfectly prepared to believe the dramatic result obtained, it would require considerably more evidence than the author records to prove that the response was of a specific nature.

The filter-passing form of tubercle bacillus is not so well established as is suggested by Dr. Crofton who states that no acid-fast granules can traverse Chamberland L₂ candles. Harry Plotz has shown that tubercle bacillus can traverse the Chamberland candles and the demonstration by Saenz, Bequet and others of acid-fast organisms in normal guinea-pigs has still further weakened the virus theory of Fontes, Valtis and others.

Carrel, Heagen, Maitland and Ledingham have never been able to change the Paschen bodies into bacilli. Dr. Crofton has not apparently attempted to repeat the work of these people.

It is not clear whether the organisms isolated by Dr. Crofton are unknown to modern science or are those microbes whose special properties are not known to any scientist of repute. It is true that Ledingham has demonstrated that the virus of Agalactia can grow in the form of a streptothrix and Bedson has worked out the life cycle of Psittacosis virus, but, out of all the known streptothrices, not one has been shown to produce malignant diseases.

There is not sufficient space in a review to deal with many of the points raised by Dr. Crofton. Had these theories been presented with scientific calmness and without obvious contempt for other workers and their

findings, this book would have proved a valuable stimulus for further work on virus diseases.

C. L. P.

DIETETICS (HEALTH THROUGH RATIONAL DIET INCLUDING PRACTICAL HINTS ON BALANCING CEYLONESE DIET)—ALSO GIVING THE NUTRITIONAL VALUES AND PROPERTIES OF FOOD-STUFFS.—By B. S. JAYAWARDENE, L.R.C.P. & S. (Ed.). Printed by the Associated Newspapers of Ceylon, Limited, Lake House, McCallum Road, Colombo. Pp. 49. Price, As. 6

This small brochure of some 49 pages is full of a number of axioms about food, breathing exercises, and personal hygiene generally. For the modest sum of six annas a considerable amount of general information is supplied which should be of value to the layman, and Indian in particular, about healthy living. We cannot agree, however, with all the statements about food which he has quoted. Meat, for instance, is said 'not to be essential for health'; this is far from proved

as applied to the majority of mankind living in any part of the globe. Further, the low stature of the Eskimo is attributed quite unjustifiably to an almost exclusive meat diet. Apart, however, from a certain number of rather sweeping and to a certain extent uncritical statements the book as a whole is worth the money.

BOTANY. (CATECHISM SERIES.) PART I. Fourth Edition. E. and S. Livingstone, Edinburgh. Pp. 76, with 30 figures in the text. Price, 1s. 6d. Postage, 2d.

H. E. C. W.

This is really a good piece of work. The author has endeavoured to write a book on botany covering all fundamental principles in the briefest manner possible. The catechism will be of great help and a good guide to beginners. Indeed, it would have been very valuable to the students of this country, had there been some examples from Indian flora.

S. M.

Abstracts from Reports

HEALTH BULLETIN ON THE VALUE OF INDIAN FOODS AND THE PLANNING OF SATISFACTORY DIETS

IMPROVING INDIA'S FOODS

An analysis of some 200 common Indian foods, prefaced by a summary of modern ideas about diet, is given in the *Health Bulletin* on 'The Nutritive Value of Indian Foods and the Planning of Satisfactory Diets' just issued by the Director, Nutrition Research Laboratories, Coonoor. The publication is a part of the move to popularize the results of nutrition researches. In the early years of nutrition work the first objective was to get together the scientific data on which practical work could be extended to the homes of the people. This material has since been collected by the workers at the Nutrition Research Laboratories, and is now being made available to the public.

An account is first given of calorie requirements and standards suitable for the various age and sex groups in India are suggested. Next, protein, fat, and various vitamins and minerals are dealt with, with special emphasis on the minimum requirements of each. Malnutrition and effect of cooking on nutritive value are also discussed.

Here is an interesting excerpt from the section on malnutrition:—

A well-balanced diet is essential if growth and development are to take place normally. A badly-fed child is often small for its age and thin; its 'weight and height' will be below average. It will fall sick easily. The frequency of minor ailments in school children can be reduced by improving the diet. A certain apathy, a lack of 'pep', of enthusiasm for work and play, is characteristic of the malnourished. The state of the skin is a sensitive index of faulty feeding; a rough dry skin, or a skin covered with a papular eruption, suggests faulty feeding. Everybody knows that a well-fed animal exhibits a certain glossiness and silkiness of fur—a 'good coat'—which is not seen in poorly-fed animals. Similarly a well-fed human being has a glossy skin and a glow of health. Bright clear eyes are also a sign of satisfactory feeding. The section on the planning of diets describes the differences between 'ill-balanced' and 'well-balanced' diets, and the methods to be followed in improving Indian diets of poor quality, and how diets can be improved without great increase in cost is described. The details given are, therefore, likely to be of considerable

able interest to the public, in particular to those who are in charge of catering in institutions and schools. Stress is laid on the value of what are called the 'protective' foods.

Human beings, and particularly children, says the bulletin, cannot thrive at their best on a diet largely composed of cereals, such as rice, millet, etc., and insufficiently supplemented by other foods. To make fair quantities of foods like milk, green vegetables, eggs, fruits, etc. These are sometimes known as the 'protective'* foods, since they are rich in proteins, vitamins and mineral salts, and protect the body against the ill which result when the diet is largely based on less nutritious foods, such as milled rice. Cod-liver oil, which is very rich in vitamins A and D, may be classed as a most valuable 'protective' food.

In general, diets in India are defective because they do not contain 'protective' foods in sufficient abundance. The aim in public health nutrition work is general and planning 'well-balanced' diets must be to increase intake of 'protective' foods. The classes in the community which are particularly likely to suffer if their diet is defective are infants and growing children and expectant and nursing mothers.

Even a little milk, which is better than none. The value of skimmed milk, which is considerably cheaper than whole milk, but contains most of its valuable elements, is emphasized. Information is given in tabular statements about protein, fat, carbohydrate, fibre, calcium, phosphorus, iron, and vitamins, and appendices are added with data about the biological value of the proteins of various foods, and the availability of iron in certain foodstuffs.

There are, of course, many kinds of public health nutrition work besides the planning of adequate diets. The task of the nutrition worker is often to make special additions (e.g., milk, cod-liver oil, various vitamin-rich preparations) to an unsatisfactory diet rather than to plan the whole diet afresh. Infant feeding is a special subject demanding special knowledge and training. But in all branches of practical dietetics the fundamental principles involved are the same, and an understanding of them is essential for successful work in this field.

It is not only the poor, whose choice in the matter of food is extremely limited, who are ignorant and *The word 'protective' is used here in a much wider sense than usual; proteins, as such, are not usually included amongst 'protective' foods. We do not think that Dr. Aykroyd himself used it in this very wide sense.—Editor, J. M. G.

prejudiced about diet. Plenty of people in India and elsewhere, who could afford themselves to consume and could feed their children on an excellent diet, do not in fact do so. One can readily find, among children of the more prosperous classes, cases of serious malnutrition and food-deficiency disease.

In drawing up the new diet schedule, or in assessing the value of an existing schedule, it is essential to know whether enough food is being provided. It might be thought that it is easy enough to discover food deficiency, for such deficiency must cause hunger. But experience has shown that human beings can adapt themselves, at a low level of vitality and with their powers impaired, to an insufficient ration, and scarcely realize that they are under-fed. The nutrition worker, in setting up standards of food requirements, ignores this remarkable faculty of the body to adapt itself to semi-starvation. His standard of food intake implies full satisfaction, enough to enable human beings to lead an energetic life at a reasonably high level of working capacity.

Dr. Aykroyd, Director of the Nutrition Research Laboratories, states in an introduction that the purpose of the bulletin is to summarize available knowledge about the nutritive value of Indian foodstuffs for the benefit of public-health workers, medical practitioners, superintendents of residential institutions and others interested in practical dietetics.

By its wealth of details the bulletin is a rich source of educational and propaganda material for those whose task it is to try and improve the health and well-being of the people, both young and old.

Public Health Commissioner.

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR THE YEAR 1934

PUBLIC HEALTH IN INDIA

IN an area of 890,000 square miles, the mid-year estimated population was nearly 276 million with a density of 310 per square mile. Births during the year numbered nearly 9½ million, and deaths a little over 6½ million, the rates per mille being 34 and 35 respectively, with the infantile mortality figure per 1,000 live births at 187.

The year presented no markedly unusual features in regard to health conditions. The death rate is higher than it was last year, and so is the infantile mortality rate, while the birth rate is lower. But such fluctuations in the recorded deaths must be expected from the present system of registration and too much stress should not be laid on them.

LIVE BIRTHS

The crude birth rate during the year was 33.7 per mille of the total estimated population as against 35.5 per mille in 1933 and 35 per mille the quinquennial mean. Including still-births, the rate was 34.3. Live births registered during the year were 4 per cent less than the figure of 1933. Compared with 1933, the Punjab recorded a decrease of a little over less than 100,000 births or of 10 per cent, the United Provinces nearly 120,000 or 7 per cent, Bihar and Orissa 79,000 or 6 per cent, and Madras 70,000 or 4 per cent. In Delhi, Bengal, Bombay, Assam and Ajmer-Merwara there were slight decreases. Small increases occurred in North-West Frontier Province, the Central Provinces, Burma and Coorg.

Birth rate calculated on the basis of the estimated number of women of child-bearing age, taken as 15 to 40 years, was 167 per mille for the whole of British India. Of the provincial figures, that for the Punjab, namely 215, is the highest. The Central Provinces is second with 209, and Delhi third with 197. The figures for the other major provinces are as follows: North-West Frontier Province 156, United Provinces 179, Bihar and Orissa 157, Bengal 139, Bombay 172, Madras 163, Assam 153, and Burma 144. The period of 15 to 40 years is possibly pitched too high, particularly for the southern half of India, but it is probably correct in

indicating a child-bearing period five years shorter than the European one.

Of the total births, 17.5 per mille were male, 16.1 female. The excess of males over females born is a constant feature. Taking British India as a whole the number of males born per 100 females is 108. Amongst the provinces this figure is 129 in North-West Frontier Province, 119 in Ajmer-Merwara, 113 in the United Provinces, and 112 in the Punjab. The other provincial figures vary near about the British India mean except that the figure for Burma is 104.

The birth rates for the whole of British India in rural and urban areas were the same, namely 34 per mille, but amongst the provinces the rural rate continued to exceed the urban in the Punjab (+6 per mille), Bihar and Orissa (+13 per mille), Bengal (+8 per mille), Bombay (+2 per mille), and Madras (+15 per mille). In other provinces it was lower. The high rural rates in Bihar and Orissa and Bengal are mainly due to the fact that a large proportion of the rural population who have migrated to urban centres return to their rural homes for child birth.

The birth rates for the chief communities, which are available for ten provinces, were as follows:—

Hindus Mohammedans Christians

North-West Frontier Province	28	31	31
Delhi	37	43	21
United Provinces	37	37	10
Bihar and Orissa	34	33	21
Bengal	28	29	20
Central Provinces	40	41	19
Madras	36	38	33
Coorg	26	19	20
Burma	17	28	23
Ajmer-Merwara	35	34	7

As usual, the birth rate exceeded the death rate in every province, the largest difference being recorded in the Punjab (+12 per mille), Madras (+11 per mille), Assam (+11 per mille), North-West Frontier Province (+10 per mille), Bombay (+10 per mille), United Provinces (+9 per mille), and Burma (+9 per mille).

DEATHS

Compared with 1933 and quinquennial mean, the death rate of 24.9 per mille increased by roughly 3 per mille and by 1 per mille, respectively. These figures reflect the relative unhealthiness of the year, particularly in Bihar and Orissa, the Central Provinces and the United Provinces, where the rates exceeded those for 1933 by 13 per mille, 10 per mille, and 8 per mille, respectively. Slightly higher mortality was returned also in Madras, Burma and Ajmer-Merwara. Female mortality exceeded male mortality in the Central Provinces (+3 per mille), Bihar and Orissa (+2 per mille), and in North-West Frontier Province, United Provinces, Madras, and Burma (each +1 per mille). But taking India as a whole, the male mortality was greater than the female, the respective figures being 25.1 and 24.6.

Mortality from the principal epidemic diseases increased during this year. Deaths from cholera, which were nearly 200,000, have been nearly three times what they were in 1933. Plague mortality which was 80,000 is almost double, but deaths from smallpox numbering about 84,000 is low. The other principal causes of death show comparatively little change. But in the main the figures are higher, particularly under the heading fevers, while the deaths recorded, numbering about 4 million, show an increase of over 400,000 over the figure for the previous year.

Health conditions for the rural population were specially unfavourable owing to the greater prevalence of fevers and cholera among them. The death rates exceeded those for urban areas by 9 per mille in Delhi, 8 per mille each in Bihar and Orissa and Madras, 7 per mille in the Punjab, 4 per mille in Ajmer-Merwara, 3 per mille in North-West Frontier Province, 2 per mille each in Bengal and Assam, and 1 per mille in the Central Provinces, while for British India as a

whole the rates were 24.9 for rural areas and 24.4 for urban areas.

The death rate for the age period, 15 to 40, was as usual higher among females than among males, and the cause is ascribable to the greater risk of death to which women are exposed during child-bearing ages, the rates being 10.7 for males and 12.4 for females.

Considering deaths by communities, the rates for the whole of British India are 28 for Hindus, 24.2 for Mohammedans and 17.5 for Christians. The provincial figures are as follows:—

Hindus Mohammedans Christians

North-West Frontier			
Province ..	15	21	14
Punjab ..	29	27	25
Delhi ..	33	25	10
United Provinces ..	26	29	5
Bihar and Orissa ..	27	23	17
Bengal ..	23	24	14
Central Provinces ..	34	32	..
Bombay ..	28	17	14
Madras ..	34	22	19
Coorg ..	22	27	..
Assam ..	18	20	18
Burma ..	21	15	14
Ajmer-Merwara ..	31	27	3

INFANTILE MORTALITY

The year 1934 was comparatively unhealthy for the infant population in India. The recorded deaths, nearly 1,700,000, were 9 per cent more than in 1933 and 10 per cent higher than the quinquennial mean; 187 out of every 1,000 born are reported to have died. The persistent high mortality of infants may be ascribed in part to defective registration not only of births but of infant deaths through the inclusion of still-births, and partly to the tendency of the more illiterate of the population to underestimate the age of the diseased infant.

The provinces chiefly contributing to the increased mortality were the United Provinces (+39 per cent), Bihar and Orissa (+11 per cent), the Central Provinces (+26 per cent), Burma (+14 per cent), and Ajmer-Merwara (+14 per cent). Minor increases also occurred in Bombay and Madras Presidencies and in Assam.

The wastage of infant life calculated in live births was the highest in the Central Provinces, Ajmer-Merwara, Burma, and Delhi. In these provinces one child in every four or five of recorded births failed to survive the first year of life, whilst the percentage of deaths of one week and above was high in Bengal, Madras, Coorg, and Assam, that in Burma was high among infants aged 1 to 6 months, probably due in part to the local custom of partial feeding at too young an age with rice pre-masticated by the mother. As in previous years, the steady fall in mortality accompanies the monthly increase in age of infants from 1 to 12 months. These figures suggest that besides defective registration, skilled maternity or midwifery service is inadequately or poorly provided, specially in the rural tracts, and that the indigenous *dai* as she is much cheaper is still in popular demand. The uniformly low death rate among Christians lends support to this view, as the majority of Hindus and Muslims still follow the primitive methods.

The poor nutrition of the mother, over-crowding, a high birth rate and high maternal mortality rate, frequent prematurity, and the prevalence of respiratory diseases, convulsions, malaria and syphilis, combined with widespread ignorance of infant management, all contribute to the great loss of infant life in India. Birth rate, as also infantile death rate, is high among the poorer classes owing to the inaccessibility to them of efficient medical service.

Figures are available for some provinces to show the chief causes of infantile mortality. In Delhi, for instance, febrile and respiratory diseases were responsible for the largest number of deaths. In the Central Provinces debilitating influences, dietetic errors

and deficiencies, malaria, maternal pre-natal weakness and neglect, bad housing, high birth rate, lack of medical aid and ignorance of the bringing up of infants are stated to be the main contributory factors. In Bombay city debility, malformation and premature birth and respiratory diseases appear to be responsible for the largest number of deaths.

The recorded still-births for British India were 19.9 per mille of live births. This figure as also the provincial figures cannot, however, be regarded as accurate, as owing to defective registration many still-births are included in the infantile mortality returns. The infantile mortality figures for the different classes of population are recorded in seven provinces only and are given below. It will be noticed that a uniform low death rate among Christians continued to be reported from these provinces:—

Hindus Mohammedans Christians

North-West Frontier			
Province ..	181	132	77
Punjab ..	194	183	165
Delhi ..	237	171	145
Bihar and Orissa ..	155	136	138
Madras ..	209	183	127
Coorg ..	187	218	75
Ajmer-Merwara ..	231	258	102

The rural and urban infantile death rates for British India were 183 and 218 per mille of live births. The urban mortality of infants in the Punjab has declined steadily during the last three years. The urban mortality figures were particularly high in Ajmer-Merwara where it exceeded the rural rate by 149 per mille, and in the United Provinces and Bombay where it was higher by 96 and 63 per mille, respectively. The rural death rates were higher than urban in Coorg, Delhi, Assam, Burma, and the Punjab, the persistently low urban rate in Coorg being due to the presence of a large number of plantation labourers who leave their families at home.

Of the total registered deaths in British India, 42 per cent as against 45 in 1933 occurred among children under 5 years of age, and 6 per cent among those aged 5 to 10 years. In other words, nearly half of all those who died were children under 10 years of age. The percentage, however, shows a drop of 2 from the previous year's figure, which was 50.

HOW INDIA COMPARES WITH OTHER COUNTRIES

	Birth rate per mille	Death rate per mille	Natural increase per mille	Infantile death rate per 1,000 births
British India ..	33.7	24.9	8.8	187
England and Wales ..	14.8	11.8	3.0	59
Scotland ..	18.0	12.9	5.1	78
Belgium ..	16.0	12.2	3.8	82
Czechoslovakia ..	18.8	13.2	5.6	126
Denmark ..	17.8	10.4	7.4	64
France ..	16.1	15.1	1.0	69
Germany ..	18.0	10.9	7.1	66
Hungary ..	21.4	14.4	7.0	150
Italy ..	23.2	13.1	10.1	99
Netherlands ..	20.7	8.4	12.3	43
Norway ..	14.8	9.8	5.0	..
Portugal ..	28.4	16.6	7.8	..
Roumania ..	32.4	20.7	11.7	182
Spain ..	26.2	15.9	10.3	113
Sweden ..	13.7	11.2	2.5	47
Switzerland ..	16.2	11.3	4.9	46
Canada ..	20.4	9.4	11.0	72
New Zealand ..	16.5	8.5	8.0	32
South Africa (White) ..	23.5	9.7	13.8	62
U. S. A. ..	17.1	11.0	6.1	60
Japan ..	30.0	18.1	11.9	125
Egypt ..	40.0	26.6	13.4	166

These figures show that the only countries with which there can be any comparison with British India on the point of birth rate are Japan, Egypt and Roumania. In the death rate again it is only Egypt which is worse than India. So far as infantile mortality is concerned, the only countries having rates at all comparable with those of India are Roumania, Hungary, Egypt, Portugal, Czechoslovakia, and Japan.

CAN INDIA SUPPORT AN INCREASED POPULATION?

In the report for 1933 it was stated that by 1941, at a conservative estimate, the population of India will probably considerably exceed the figure of 400 millions. This is considered once again and the conclusion arrived at is that the figure of 400 millions mentioned in last year's report is likely to be near the mark.

The question, therefore, arises 'Can increased population be balanced by increased good production?' In dealing with this question, there are several points to bear in mind. Agricultural research is continuously showing the way to increased yields. There are areas under wheat yielding 14 maunds to the acre which could be made to yield double that amount. In the present state of our knowledge, it is not safe, therefore, positively to assert food production cannot keep pace with the increase in population. Although there is evidence of widespread under-nutrition in India, there is nothing to show that the ryot is worse fed now than he was in earlier days. Rather is it probable that the absorption of food-stuffs has over a period of years risen in proportion to the population. Another factor which has a bearing on the population question is the relation of the birth and death rates. To those who believe that improved economic conditions or a rise in the standard of living will be followed by a drop in the birth rate there is some evidence that economic conditions are improving, while for those who hold that sooner or later increasing density will, by means which have not yet been satisfactorily demonstrated, lower fertility, there may be some consolation in the undoubted fact that population density is increasing in India. One other important factor in connection with the birth rate is the age of marriage. There is a considerable volume of opinion among those qualified to judge that the age of females at marriage is rising; this rise will tend to reduce fertility and therefore lower the birth rate.

If food production keeps pace with population increase, a critical situation may be avoided. But India needs more than this. A higher standard of living, with all that this brings in the way of improved health and welfare, is a pressing need. This can only be secured, in a predominantly agricultural country, by a considerable increase in food production or a pronounced drop in the annual increment of population.

NUTRITION

But whatever may be the solution of the population problem in India, no one will deny that our large annual increase in population requires that attention should be directed to a greater extent than has hitherto been the case on the important subject of nutrition. A great deal of research has been carried out in the nutrition research laboratories of the Indian Research Fund Association at Coonoor, and the results of this research require to be made known to the public. Over and above this there is need for an investigation into the state of nutrition and dietary habits of the people on which our information is lamentably deficient.

RURAL HYGIENE

Sanitary improvement in rural areas, where the vast majority of the people of India live, is one other outstanding need of the country. In these areas, educationally, socially and materially backward as the people are, compared with those in urban areas, general sanitation is still in a primitive condition. Medical relief for the most part is grossly inadequate and maternity and child-welfare works are almost completely lacking.

A beginning has, however, been made in a number of areas. Rural health units are now being established and are likely to be of great assistance, both as experimental stations for trying out schemes of village improvement and as demonstration and educational centres.

AERIAL NAVIGATION AND YELLOW FEVER

A potential danger to the public health of India is the possibility of yellow fever coming in. And this danger has become acute as a result of the recent development of rapid aerial communication between India and Africa, the main endemic home of yellow fever, which is now only a few days distant in time from India; an infected person embarking on a plane in Africa can now arrive in India in the infective stage of the disease. Should yellow fever happen to be introduced into India, the disease would be so appalling that it may well cripple the country for a generation. All the necessary factors for the rapid spread of the disease if the virus be introduced are present, and it is essential that precautionary measures should forthwith be taken. These consist in freeing the cities, and particularly the seaboard towns, of the stegomyia mosquito and in establishing adequate quarantine facilities for isolation of suspected cases and their contacts in mosquito-proof buildings at the airport of entry in Karachi. Fortunately quarantine measures have already been taken at Karachi and are in progress.

(To be continued in the next issue)

THE SIXTEENTH ANNUAL REPORT OF THE BLIND RELIEF ASSOCIATION, BIJAPUR, 1935

THE association was started in the year 1920 and owes its existence to the solid support and enthusiasm of the people of Bijapur District. It is the first philanthropic association of its kind in the Karnatak and was established for the prevention and cure of blindness primarily in the District of Bijapur, and funds permitting, in the surrounding Districts and States also.

From the incidence of blindness in the Karnatak it can be judged that whatever be the cause of blindness no less than 30 to 40 per cent of these cases are remediable and an equal number preventable. For this purpose we have been carrying on propaganda work amongst the village population by lectures and magic lantern demonstrations on personal hygiene and village sanitation, and are hunting out cases of diseases such as smallpox and measles which are likely to give rise to serious eye afflictions.

Baby Week Shows and Village Maternity and Child-Welfare Centres should have a place for the eye, where attempts can be made to impress on the minds of the public the importance of eyes, their susceptibility to infections, and the possibility of preventing such infections, if care is exercised at the proper time. This principle has been specially observed in this district by the introduction of a special stall at these shows exhibiting the various common eye ailments, explaining their common causes by various charts, pamphlets, posters and also arranging a small exhibition of the common remedies and precautionary measures, which could easily be practised by the public and thus the onset of eye afflictions and their sequelæ averted.

Preventive work has been carried out by this association through its field workers in the villages of the district for the last 17 years. This has done immense good to thousands of poor patients. The association offers certain special facilities to the poor and deserving patients. Among such facilities may be mentioned journey charges to and from the civil hospital, supply of food and clothing during their stay and a pair of spectacles for those operated on, in addition to the free medical and surgical treatment. In spite of all such facilities, patients very often keep away for want of proper education, ignorance and superstition. Occasions are not infrequent when they have to be persuaded to undergo treatment.

There were eleven field workers, one for each of the eight Talukas, viz, Bijapur, Indi, Sindgi, Bagewadi,

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL E. W. C. BRADFELD, C.I.E., O.B.E., K.H.S., Officiating Director-General, Indian Medical Service, is confirmed in his appointment, with effect from the 1st March, 1937.

Lieutenant-Colonel W. E. R. Dimond, Assistant Director of Public Health, North-Western Frontier Province, is appointed to officiate as Inspector-General of Civil Hospitals and Inspector-General of Prisons of that Province, with effect from the 14th January, 1937, till further orders.

Lieutenant-Colonel J. M. R. Hennessy, Civil Surgeon, Jubbulpore, is appointed to officiate as Inspector-General of Civil Hospitals, Central Provinces, *vice* Colonel N. M. Wilson granted leave, with effect from the afternoon of the 17th February, 1937, till further orders.

Lieutenant-Colonel D. H. Rai, M.C., is appointed to officiate as Inspector-General of Civil Hospitals, Punjab, with effect from the 12th March, 1937, or the date on which he may assume charge, *vice* Colonel C. H. Reinhold granted leave.

Lieutenant-Colonel T. D. Murison, Director of Public Health, Assam, is appointed to officiate as Inspector-General of Civil Hospitals and Prisons, Assam, with effect from the afternoon of the 31st March, 1937, till further orders.

Lieutenant-Colonel F. J. Anderson, Professor of Surgery, Medical College, Calcutta, is appointed to act as the Principal, Medical College, Calcutta, in addition to his own duties for the period from the 8th April, 1937, to the 20th May, 1937, *vice* Lieutenant-Colonel T. C. Boyd granted leave.

Lieutenant-Colonel H. E. Murray, when appointed as Professor of Midwifery, Medical College, Calcutta, in place of Lieutenant-Colonel P. F. Gow, will act as the Principal, Medical College, Calcutta, in addition to his own duties for the period from the 21st May to the 9th June, 1937, *vice* Lieutenant-Colonel T. C. Boyd granted leave.

Lieutenant-Colonel H. E. Shortt, Officiating Director, King Institute, Guindy, is confirmed in that appointment, with effect from the 13th August, 1936, *vice* Lieutenant-Colonel H. H. King retired.

The services of Lieutenant-Colonel R. C. Clifford, M.C., D.S.O., are placed at the disposal of the Chief Commissioner, Delhi, for appointment as Civil Surgeon, New Delhi, with effect from the forenoon of the 15th February, 1937.

Major G. C. Maitra, an officer of the Medical Research Department, at present officiating as Director, Pasteur Institute, Rangoon, is confirmed as Director, Pasteur Institute, Kasauli, with effect from the 13th August, 1936, *vice* Lieutenant-Colonel H. E. Shortt. He will continue to be employed as Officiating Director, Pasteur Institute, Rangoon, until further orders.

Major T. H. Thomas, on leave from leave, is appointed, until further orders, to act as Professor of Medicine, Medical College, and Physician, College Hospitals, Calcutta, *vice* Lieutenant-Colonel E. H. V. Hodge.

Major T. H. Thomas, when appointed to officiate as Professor of Medicine, Medical College, Calcutta, in place of Lieutenant-Colonel E. H. V. Hodge, will act as the Superintendent of the Medical College Hospitals in addition to his own duties during the absence on leave of Lieutenant-Colonel T. C. Boyd, for the period from the 8th April to the 9th June, 1937.

The services of Captain Said Ahmad are placed temporarily at the disposal of the Government of the United Provinces, with effect from the forenoon of the 5th February, 1937.

Captain E. A. O'Connor, an Officiating Agency Surgeon, is posted as Medical Officer, Meshed, with effect from the afternoon of the 20th February, 1937.

Muddebihal, Bagalkot, Hungund and Badami, one for Bilgi Petha, and one has been entirely working in the municipal area of Bijapur. A special field worker has been maintained at Akalkot. The field workers have been specially trained at the civil hospital in washing the eyes and the management of common diseases. They are in a position to recognize any serious affliction requiring operative treatment and are instructed to send such cases to the nearest dispensary or camping place of the touring medical officer or the civil hospital, according to the seriousness of the complaint and the treatment required for them. Each field worker is given charge of a number of villages. He tours these villages by rotation, finds out cases for treatment by house to house visits, treats them and gives them medicines for further treatment during his absence.

On his rounds, if he comes across cases of blindness which are not curable, he takes them on his register which enables us to collect proper statistics about the incidence of blindness in this district. He also inspects births for ophthalmia neonatorum. On an average he can visit two to three villages in a day. The field workers are supplied with ponies and they carry with them a box which contains solutions of boric acid, silver nitrate, sodium chloride, argyrol and mercury and dionine ointments, some cotton-wool, a bowl and a kidney tray. They maintain a record of their work in special registers supplied to them. The total number of cases treated by them during the year was 22,991.

Birth inspection is an important portion of preventive work. The total number of birth inspections done by the field workers during the year was 24,889 and the separate record of births examined within ten days of birth is also kept and the number of children so examined was 3,726. The examination was repeated within 10 days in the case of 632. The number of treatments done in the course of these examinations of children under one year of age for ophthalmia neonatorum was ten and for other diseases 6,142. The number of cases of eye diseases among children under five years of age detected and treated was 6,036. Amongst these five were cases which required surgical interference and had to be sent to the civil hospital.

[It is evident from this abstract that this association is carrying on valuable work and its example might be followed with advantage in almost any other part of India.]

Correspondence

AN UNUSUAL RESULT OF AN ACCIDENT

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—A boy, aged about eight years, was knocked down in a motor accident and run over by a motor bus. A wheel is said to have passed over him.

He was brought dead to the hospital and the post-mortem examination revealed ruptures of the liver, spleen, lungs, and right kidney; the abdomen was ruptured and the intestines protruded therefrom.

The thorax was severely crushed and laid open. The heart was found lying free in the thoracic cavity and completely detached from all its blood vessels. This is a rare thing. Many cases of ruptures of the spleen, liver, kidney, intestines, etc., are observed in motor or railway accidents, but the entire detachment of the heart from the blood vessels is a rarity and therefore this letter is sent for publication.

Yours, etc.,

S. D. MEHTA, M.C.P.S., B.M.S.,
Lecturer in *Materia Medica* and
Jurisprudence, Civil Hospital.

AHMEDABAD,
19th March, 1937.

LEAVE

Brevet-Colonel R. N. Chopra, C.I.E., K.H.P., Officiating Director and Professor of Pharmacology, School of Tropical Medicine, Calcutta, is granted leave, *ex-India*, for 1 month, with effect from the 15th July, 1937, and is permitted to prefix the summer vacation of the School from the 16th April, 1937, to the 14th July, 1937, to the leave.

Lieutenant-Colonel T. C. Boyd, Principal, Medical College, and Superintendent, Medical College Hospitals, Calcutta, is granted leave, *ex-India*, for the period from the 8th April, 1937, to the 9th June, 1937.

Lieutenant-Colonel E. H. V. Hodge, Professor of Medicine, Medical College, and Physician, College Hospitals, Calcutta, is granted leave for 6 months with effect from the 9th April, 1937.

Lieutenant-Colonel S. A. McSwiney, Officiating Professor of Obstetrics, Medical College, Calcutta, is granted leave for the period from the 13th to 20th October, 1937, in extension of the leave already granted to him.

PROMOTIONS

Majors to be Lieutenant-Colonels

- S. L. Patney. Dated 2nd February, 1937.
D. N. Bhaduri. Dated 4th February, 1937.
B. Basu, O.B.E. Dated 5th February, 1937.
M. A. Jafarey. Dated 25th February, 1937.
G. Verghese. Dated 27th February, 1937.
A. D. Loganadan. Dated 27th February, 1937.

RETIREMENTS

Major-General Sir Cuthbert Allan Sprawson, Kt., C.I.E., K.H.P. Dated 1st March, 1937.

Major-General A. W. M. Harvey, K.H.S. Dated 9th February, 1937.

Notes

THE TREATMENT IN BAD-NAUHEIM, GERMANY

LIFE under present-day conditions demands healthy, brave and happy people. But simultaneously, life makes heavier calls on the energy of man, and this must inevitably place a great strain on the heart. A course of treatment in watering-place for heart affections, on the first signs of heart complaints, or in their more advanced stages, has, therefore, won enormously in importance. As a rule, heart complaints can be traced back to other diseases, it adds enormously to the importance of the world-renowned watering-place Bad-Nauheim that its rich store of healing powers not only combat the effects of a given complaint, but also serve to remove the original causes. The natural heat of the soils and its brines in various amalgamations and structures, supplemented by all the resources of medical skill, constitute the basis for the celebrated therapeutics of Bad-Nauheim. The beneficial effects are not confined to the treatment of heart complaints; on the contrary, the unique and beneficial effects are equally striking in cases of rheumatism, complaints of metabolism, complaints of the respiratory organs and nervous system and for a state of exhaustion.

In the town itself he is surrounded by the stillness and peaceful rest which are absolutely essential, if the healing mediums are to do their work to the full. But more than all this, the guests are always ready to confess that Bad-Nauheim itself is a veritable experience which will always be numbered among the pleasantest remembrances in life.

'TABLOID' BRAND SULPHONAMIDE-P, 0.5 GM.
(P-AMINO BENZENESULPHONAMIDE)

'TABLOID' brand sulphonamide-P, 0.5 gm., recently issued by Burroughs Wellcome and Company, presents

p-aminobenzenesulphonamide for administration by mouth in hæmolytic streptococcal infections. It has been shown experimentally that, following administration of this chemotherapeutic substance, the blood of man and animals becomes bactericidal to hæmolytic streptococci. The clinical evidence available pending the publication of the results of official trials is favourable although limited.

Before deciding to use 'Tabloid' sulphonamide-P in the treatment of severe streptococcal infections, such as puerperal septicæmia, erysipelas, etc., it is suggested that patients should be submitted to full bacteriological examinations to establish clearly the presence of hæmolytic streptococci in the lesion or in the blood stream. 'Tabloid' sulphonamide-P should be administered orally in a total daily dose of six to ten 0.5 gm. products after meals, the full dosage being continued for six days after the temperature becomes normal. In the event of some gastric disturbance following large dosage—the only troublesome symptom so far reported—the dose might be reduced temporarily. 'Tabloid' sulphonamide-P may be tried intramuscularly when oral administration is found to be impossible. In such a case the low solubility of the substance (1.2 per cent) makes the total amount that can be conveniently given by this method undesirably small. For intramuscular injection one 'Tabloid' product should be boiled up in 40 c.cm. of 0.7 per cent saline, and the solution cooled to body temperature before injecting. Clinicians using sulphonamide-P are invited to send reports for consideration with those of the official trials.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.
